The vast experience of European observers during the recent war also showed that undernourishment causes decreases in blood pressure and pulse rate in both normal and hypertensive subjects. During recovery, the blood pressure not only returns to normal levels, but may rise to frankly hypertensive levels The extensive observations made in Leningrad before the outbreak of the war and during and following the great siege, are characteristic. During the period of reduced food intake, the incidence of hypertension decreased and, in a large number of hypertensive patients, reduction of blood pressure to normal or near normal levels occurred. This was accompanied by a definite decrease in the incidence and intensity of symptoms commonly associated with hypertension; and precordial pain and myocardial infarction were encountered less often than before the war. With an improved food supply, the incidence of hypertension reached epidemic proportions while the incidence of cardiac insufficiency in hypertensive patients increased. In some hypertensive patients, the disease became much more severe in the poststarvation period than it had been in the presiege period.

Although the primary causative factor appears to be the limitation of total calories, cholesterol and total fat restriction were also significant factors. Since salt intake was not especially restricted, this element was of no special significance in any of these studies

NUTRITIONAL EDEMA. When protein deficiency progresses, a disturbance of nitrogen balance develops, as well as reduced serum protein concentration. Hypoproteinemia leads to generalized edema. The deficient diet is be-

rhea, draining fistula, gastric suction, and repeated use of mercurial diuretics), and sprue Studies on familial periodic paralysis and diabetic acidosis have contributed toward the correlation of electrocardiographic changes and hypopotassemia. The electrocardiographic alterations include *prolongation of the Q-T and P-R intervals*, flattening or inversion of the T wave, depression of the S-T segment, decrease in the amplitude of the QRS complex, intraventricular block, or the occasional appearance of prominent U waves

In hypocalcemic states, such as occur in hypoparathyroidism, acute pancreatitis, sprue, and uremia, the electrocardiogram characteristically shows a *prolongation of the Q-T interval*. A borderline calcium deficiency may be further reduced below the critical level by excessive diuresis caused by mercurial diuretics, coffee, or diabetes

The *trace elements* include magnesium, boron, manganese, iron, copper, cobalt, zinc, phosphorus, iodine, and fluorine The role of trace elements is one of participation in the activities of hormones and enzymes, a role probably analogous to that of the vitamins The catalytic-synergistic action of these minerals with vitamins probably makes the difference in speeding up enzymatic processes upon which the body is dependent for all of its functions Deficiencies of minerals and trace elements may affect virtually every organ Unfortunately, knowledge concerning the effects of the trace elements on the cardiovascular system is quite meager at present

Overnutrition. Overnutrition generally implies an excessive caloric intake which results in obesity Hypervitaminosis D and the effects of excess inorganic elements are appropriately considered in this connection

OBESITY Obesity is a metabolic disturbance which is characterized by the ingestion of calories beyond the normal bodily energy requirements resulting in the deposition of excessive adipose tissue There are approximately 30 million overweight persons in the United States alone Obesity produces anatomic and functional impairment of the heart This places a greatly increased burden upon the cardiovascular system by direct invasion of these structures (fatty infiltration) or by increasing their work load Significant degrees of fatty infiltration are found in 6 per cent of autopsied adults. A weight increase of more than 10 lb produces a marked increase over the expected mortality, which is somewhat greater in men than in women. Actuarial statistics indicate that, because of cardiac and other complications, the average age of the obese at the time of death is only 52 1 years This increased death rate is due, principally, to degenerative diseases owing to such factors as increased resting work fraction of the total metabolism, cardiovascular strain, and the frequency of glycosuria. Fatty hearts are present in the majority of patients with diabetes, and diseases of the gall bladder, liver, or pancreas. Both the internist and surgeon are repeatedly impressed by the fact that the obese patient is more prone to complications following medical or surgical conditions For example, thromboembolic episodes are known to have a far greater incidence among the obese

Excessive food intake usually reflects heredity or family conditioning or has a psychogenic basis Lesions involving the hypothalamus may also lead to obesity It may be associated with endocrine disorders, such as hypothyroidism or hyperinsulinism

Dyspnea may occur on a purely mechanical basis and improves promptly with weight reduction However, the occurrence of dyspnea in the obese should not be viewed indifferently since it may be the first evidence of cardiac embarrassment Considerable controversy still exists as to whether obesity is a factor in hypertension The evidence seems to favor the view that an elevation of both systolic and diastolic blood pressures is a common occurrence in obesity Furthermore, overweight may aggravate a preexisting hypertension, and a moderate drop in blood pressure occurs following weight reduction. Clinical findings associated with coronary sclerosis are much more common in obesity than in control series. When death occurs unexpectedly, it is believed that the circulation has proved inadequate following strain of the cardiovascular system caused by infections, surgery, or other stresses Electrocardiographic findings may reveal low amplitude of the QRS complexes and T waves. The similarity of these findings to those seen in hypothyroidism may prove confusing. However, T-wave changes are usually more marked in the latter condition, and there may be a complete inversion of the T waves in all leads

culation of the thiamine content in the diet and the daily requirement of the patients are of dubious accuracy but may suffice to confirm clinical impressions.

Nicotinic Acid Deficiency (Pellagra). Nicotinic acid (niacin) forms a part of coenzymes I and II which are essential for glycolysis and tissue respiration. A deficiency of nicotinic acid and tryptophane in those exposed to the sun leads to the development of cellular alterations in the gastrointestinal tract, skin, and nervous system which contribute to the clinical picture of pellagra. Although almost 7,000 cases were reported in the United States in 1928, only 804 deaths occurred in 1946. This was due to many factors, the most important of which was improved public health education. Cardiovascular involvement is primarily manifested by electrocardiographic changes characterized by lowering or inversion of T waves. The administration of nicotinic acid results in a prompt return to normal. These changes are metabolic in origin, resulting from coenzyme deficiency in the heart muscle.

Vitamin C Deficiency (Scurvy). The lack of vitamin C produces the clinical picture of scurvy. The deficiency may result in hemorrhage into the various layers of the heart and blood vessels as it does into other structures. Enlargement of the heart and tachycardia may occur due to involvement of the connective tissue of the cardiac muscle. Degenerative lesions of the myocardium have been found in advanced cases. A resultant secondary anemia may also exert its effect on the cardiovascular apparatus. Advanced cases with hypertrophy of the right ventricle as well as cases of sudden death in children are on record.

Vitamin D Deficiency. A deficiency of vitamin D produces rickets, with its many characteristic skeletal deformities, as a result of the alterations in calcium-phosphorus metabolism. It produces no direct effects on the cardiovascular apparatus. However, bony deformities of the thoracic cage, such as funnel or pigeon chest and marked kyphoscoliosis, may eventually result in *chronic cor pulmonale*.

MINERAL DEFICIENCIES (ELECTROLYTE IMBALANCE). Deficiencies of various minerals may accompany serious malnutrition, but may also occur in the presence of renal or gastrointestinal diseases and certain hormonal disturbances (adrenocortical disturbances, hyperparathyroidism, and diabetes mellitus). Various electrolyte imbalances may result.

Decreased sodium and chloride intakes rarely affect a normal individual because of the efficient conservation of sodium and chloride by normal kidney function. A deliberately decreased sodium intake is an integral part of the treatment of hypertensive states and congestive heart failure. Its probable relationship to adrenal cortical hormones has been recognized. However, chronic salt restriction, further aggravated by the frequent use of diuretics may result in a serious sodium depletion which requires emergency treatment (*low salt syndrome*). A hypochloremic state may also result in refractory congestive heart failure unless it is corrected. Excessive loss of salt in hot weather may give rise to heat cramps or heat stroke.

Although *potassium* is present abundantly in most foodstuffs, a bodily depletion may result following a number of conditions. Myocardial necrosis and leucocytic infiltration followed by fibrosis, have been produced in rats and hogs by means of a diet markedly deficient in potassium, as well as by the administration of large doses of desoxycorticosterone. Similar changes have been found clinically following the treatment of Addison's disease with DOCA.

Familial periodic paralysis is a rare disorder which demands special attention. It occurs in certain families, and attacks are precipitated by a large carbohydrate meal or violent exercise. For some unknown reason, the attack is brought about by the passage of extracellular potassium into the cells of the body, thus producing a sharp drop in the potassium level of the serum. The episode of paralysis which follows a large meal may be due to the uptake of potassium by the liver as it stores glycogen. The clinical picture of *potassium depletion* consists of muscular weakness, partial respiratory paralysis, water-hammer pulse with irregular rhythm, increased pulse pressure, cardiac dilatation, a systolic murmur, and increased venous pressure. The symptoms disappear after administration of potassium. Other clinical conditions associated with low plasma potassium are diabetic acidosis, postoperative states, the cell-building phase which follows massive tissue destruction, the ion-readjustment phase following recovery from the loss of fluid containing electrolytes (diar-

The earliest changes are *elevated and peaked T waves* As serum potassium level rises, an increased P-R interval is noted, which may be followed by *atrial standstill*. Obliteration of the S-T segment with the T wave originating from the S wave is noted progressively. With still higher potassium levels, widening of the QRS complex occurs and a biphasic ventricular complex may be seen. Death finally occurs as a result of the electrolyte imbalance causing cardiac arrest or ventricular fibrillation.

and an occasional depression of the S-T segment. A deep Q wave followed by an inverted T wave in lead III is occasionally confused with posterior wall infarction. In obesity, the T waves in the unipolar precordial leads may be reduced in amplitude to 50 per cent of normal but do not become inverted. Roentgenograms may fail to reveal enlargement since fat deposited on the cardiac surface is usually not visible on the film. However, a small triangular area occasionally seen at the apex is due to a pad of pericardial fat and fibrous tissue. Sclerosis, widening, tortuosity, and aneurysmal dilatation may be visible in the aorta and the large arterial branches, when obesity is associated with marked arteriosclerosis. In extreme obesity, a considerable deposition of fat within the cardiac walls results in an increase of the transverse diameter of the heart (Fig. 16-3B).

HYPERVITAMINOSIS D. The use of large doses of vitamin D in the treatment of rickets and arthritis has resulted in a number of fatalities. The increased calcium and phosphorus levels of the blood serum result in the precipitation of calcium phosphate at abnormal sites (metastatic calcification) similar to those found with the use of excess parathyroid hormone. The pathological state is not unlike that seen in hypercalcemic states associated with hyperparathyroidism, osteomalacia, osteitis fibrosa cystica, osteoporosis, and renal rickets. Excessive *calcification of the aorta and large arteries*, with a predilection for the subintimal zone, may occasionally be seen. Experimental studies have revealed that regressive changes precede the occurrence of demonstrable calcification. The intima may be intact but frequently presents transverse ridges at the selective sites of calcification which may be covered by small thrombi. Amorphous or plate-like deposits of calcific material may be seen about the elastic fibers. In chronic cases, there is a marked fibroblastic reaction with metaplastic bone formation. The media usually shows no changes.

Secondary *myocardial calcification* (different from the primary forms) may also occur following an excessive intake of vitamin D (as well as in other disorders, e.g., Paget's disease). The valves, endocardium, annulus fibrosus, and pericardium may similarly become impregnated with calcium deposits (Fig. 16-1).

The clinical manifestations of hypervitaminosis D include symptoms due to hypercalcemia (anorexia, lethargy, constipation, and so on), as well as polyuria, polydipsia, albuminuria, hyposthenuria, impaired renal function, hypercalcemia, and hyperphosphatemia. Cardiac manifestations depend upon the nature and degree of the calcification. In rare instances, the deposits may be so diffuse as to interfere with proper contractility. Electrocardiographic changes may reveal T-wave changes and decreased voltage of the QRS complexes, as well as a *shortened Q-T interval*. Roentgenologic findings of cardiac calcification are characteristic. Calcium deposits appear as sharply delineated dense shadows. Under the fluoroscopic screen, they are seen to pulsate with the myocardial contractions. The oblique and posteroanterior views are necessary to definitely determine the exact location of the calcification. Valvular calcification usually reveals a circular motion on fluoroscopy and is sharply localized to the position of the cusps or leaflets. Other structures are more diffusely involved.

MINERAL EXCESSES. Excessive ingestion or administration of various mineral substances seldom occurs as a nutritional disorder. Calcium and phosphorus disturbances have already been discussed under hypervitaminosis D. Variations in water and sodium tend to proceed concomitantly and are controlled to a great extent by the regulatory activity of the kidneys. Excessive osmolar concentration of the body fluids occurs when a sodium-rich fluid (such as *sea water*) is ingested or excessive hypertonic saline is administered. Such cases are not uncommon during wars, when ships or planes are destroyed. When the condition can no longer be balanced by urinary excretion, water is drawn from the intracellular compartment, and this eventually results in circulatory failure. Excess of chloride concentration in the extracellular fluid may be induced by parenteral administration of saline solution when water is not ingested for one reason or another.

Hyperpotassemia may result from severe dehydration or the administration of potassium salts in severe renal insufficiency, among other medical causes. Paralysis of the voluntary and respiratory muscles occurs. The ECG is a good indicator of serum potassium levels because this ion is involved in muscular contraction

The earliest changes are *elevated and peaked T waves* As serum potassium level rises, an increased P-R interval is noted, which may be followed by *atrial standstill* Obliteration of the S-T segment with the T wave originating from the S wave is noted progressively. With still higher potassium levels, widening of the QRS complex occurs and a biphasic ventricular complex may be seen. Death finally occurs as a result of the electrolyte imbalance causing cardiac arrest or ventricular fibrillation.

Hyperergic mechanisms in cardiovascular disease

BRAM ROSE

Advances in immunology and hypersensitivity have led to a reevaluation of many diseases of obscure origin, which are now partially explained on the basis of an *immune mechanism* Some disorders of the cardiovascular system fall into this category and are believed to be due to "hyperergic," or to use the commoner term, *allergic processes*.[1] It is the purpose of this chapter to review some of the mechanisms which relate to this concept.

Theoretically, any substance capable of stimulating antibody production may be termed an *antigen*. While the majority are of proteic nature, not only may carbohydrate or lipid act in this manner, but compounds of smaller size and weight are also capable of participating in this process Many of the latter are capable of combining with one of the plasma proteins to form a complex This complex molecule is then antigenic, but the smaller radical is responsible for the specificity of the antibody so formed, and may combine with it. This is known as the "hapten" theory.

As long as a protein is foreign to the organism, it is theoretically capable of stimulating the production of antibodies The well-known immune responses which occur subsequent to invasion of the body by bacteria or other foreign organisms have been regarded as a *protective mechanism*, since antibodies to bacteria may have many attributes such as the neutralization of a toxin, or the enhancement of phagocytosis, to mention but two Their specificity permits diagnostic procedures carried out either in the test tube or in the skin These procedures depend on the fact that the antibody has an affinity for the antigen and forms a complex which, for example, can be seen as a precipitate in vitro, or the induction of a skin reaction when the antigen is injected in the skin. Immediate skin reactions consist of a flare and wheal and are due to the release of histamine The antibodies involved are humoral and circulate in the plasma Delayed responses, which take some 48 hr to appear and consist of a local erythema at the site, are due to a bacterial antibody of which that resulting from *tuberculin* is the prototype As demonstrated by Chase, this form of antibody is cellular rather than humoral. Skin reactions to tuberculin are in effect a local allergic manifestation, and will occur only if the antibody specific for the injected antigen is present. It was this altered reaction to tuberculin which prompted von Pirquet to call this phenomenon "allergy" Nevertheless, individuals giving such responses are not necessarily allergic in the ordinary sense of the term.

With the developments consequent on the description of *serum sickness* in man and *anaphylaxis* in animals, the whole concept of allergy began to take form, since it was soon realized that the common denominator of allergic disease was the combination of an anti-

[1] The interconnected aspects of "hyperergic" and "allergic" disorders, and the "diseases of the collagen system" are discussed in this and the next chapter. *Editor*

gen with its specific antibody This is, however, the basis of immunity as well. *It is difficult, therefore, to define the borderline between these two states.* There are certain general criteria which differentiate the allergic response from the immune reaction. Some of these are discussed below.

SELECTIVITY, OR HEREDITARY FACTORS

Allergic manifestations of the common variety, such as the hay-fever–asthma–urticaria variety, occur in an estimated 7 per cent of the population. The tendency is hereditary in the majority of cases. In a similar fashion, only 15 per cent of those infected with group A hemolytic streptococci develop rheumatic fever or glomerulonephritis There are many forms of hypersensitivity, however, which do not seem to follow this pattern, they occur in patients devoid of any previous allergic tendency or family history of allergy. The nature of the inherited or acquired metabolic change which allows hypersensitivity to develop is quite obscure. Clearly, other factors are often involved, particularly the nature of the antigen or the type of invading organism. For example, individuals residing close to cottonseed growing or processing develop a high incidence of allergy to this substance Similarly, Lancefield A streptococci, type III, may give rise to a much higher incidence of glomerulonephritis than other types.

ALLERGENS (ANTIGENS)

Individuals with an allergic background may develop sensitivity to substances which in general are harmless to the rest of the population These include foods, pollens of many varieties, and drugs It is clear that other antigens, such as bacteria of one sort or another, fall into this category as well. However, since not only may evidence of the infection be present but allergic manifestations, such as asthma, acute rhinitis, or urticaria as well, it is possible that some additional form of antibody response takes place in allergic patients This concept is supported by the well-known fact that almost all antigens are impure in the sense that they are complex in nature and, therefore, may give rise to multiple antibodies. Since the allergic individual is characterized by the fact that he is prone to develop antibodies easily, the response may be a different one However, the tendency to develop conventional antibodies in quantities greater than normal was not found to exist in patients with rheumatic fever. Another manifestation is the eosinophilia which accompanies most, although by no means all, allergic responses. In this connection, it is believed by Speirs that the eosinophil may give rise to antibodies, but the exact significance of this cell is not yet known.

NATURE OF THE RESPONSE

It is characteristic of the allergic or hyperergic response that the pattern of the lesion bears little or no relation to the properties of the inciting antigen. For example, polyarteritis may be precipitated by a variety of different allergens including drugs, bacterial infections, or parasitic infestations The same is true for various allergic skin lesions as well as the commoner forms of allergy such as asthma.

As will be pointed out below, it is possible to vary the response in the experimental animal by means of a selective antigen Thus, one can induce antiserums with an affinity for the various cellular elements of the blood, the kidney, and thyroid or other special tissues. Of particular importance in this whole concept is the fact that, in early experiments, it always seemed necessary to use a second species. Thus, in order to induce a form of glomerulonephritis in the dog, it was necessary to inject extracts of dog kidney into a second species, to which the tissue was foreign. The recipient of the foreign tissue would then produce an anti-dog-kidney serum which, when administered to a dog would combine selectively with kidney tissue, thereby inducing lesions. It is now possible to induce such lesions without resorting to a second species, using homologous tissue. This represents a marked advance in the study of "immune" mechanisms in terms of human allergic disease.

ANTIBODY FORMATION

It is now generally accepted that most, if not all, antibodies consist of gamma globulin with an immune specificity. The source of antibody is a question of some debate. In general, it is believed that antigen finds its way to some part of the reticuloendothelial system, there to be taken up and transferred to the

lymphocyte. In this cell, it exists in a precursor state. Whether the lymphocyte actually transfers it to the plasma cell, or indeed, as believed by Dixon, the lymphocyte is the actual precursor of the plasma cell itself, is not firmly established. It is, however, agreed generally that the ultimate source of gamma globulin or antibody, as the case may be, is the plasma cell. It seems probable that there are other sources of antibody since patients with *agammaglobulinemia,* who are also devoid of plasma cells, appear to develop skin reactions of an allergic nature as well as resistance to some viral infections.

EFFECTS OF COMBINATION AND NATURE OF LESIONS PRODUCED

The combination of antigen with antibody may give rise to a variety of effects depending on the nature of the complex, the site of combination, and the type of metabolite released. In the case of the common forms of allergy, which are due to foods, inhalants, or in some instances drugs, skin-sensitizing antibody is involved, and it is believed that *histamine,* as well as other metabolic substances, may be released at the site of combination. *The cardiovascular system participates in the reaction in that capillary dilatation and increased permeability occur in association with smooth muscle spasm* In the majority of cases, these are minor and reversible However, acute anaphylactic reactions leading to rapid *vasomotor collapse* may occur. In those cases where ECG tracings have been obtained, minor, nonspecific changes of a reversible nature have been found On a similar basis, *extrasystoles,* other forms of *arrythmias,* and *tachycardia* have been reported from time to time as being caused by certain foods

In acute animal experimentation, with the production of anaphylaxis by means of sensitization with a foreign protein, production of precipitating antibody, and eventual anaphylactic shock following the injection of the shock dose of antigen, it is now believed that the mast cell is the target organ This cell contains *histamine, heparin,* and *serotonin* (5-hydroxytryptamine). What role serotonin plays in the anaphylactic reaction is not yet clear It is released in considerable quantities during anaphylaxis in the rabbit and rat A remote but possible role for serotonin is the *induction of* valvular lesions. Thus, right-sided valvular defects, which occur in patients with the clinical syndrome of *carcinoid,* are thought to depend on the presence of large amounts of serotonin in the blood. Whether this bears any relation to the valvular lesions which occur in rheumatic heart disease or those of disseminated lupus erythematosus is unknown. Depending on the animal species used, the predominant metabolite may be histamine, as in the guinea pig, or serotonin, as in the rat. The rabbit appears to release both substances. The so-called "shock organ" also varies from one species to another. In this respect, man seems to differ somewhat since the shock organ varies from one individual to another. For example, hypersensitivity based on pollen or drugs may give rise to lesions involving the sinuses, lungs, skin, joints, or small blood vessels The reasons for this are not clear unless it be due to the actual location of the antibody in a particular tissue.

EXPERIMENTAL ARTERITIS AND CARDITIS

The induction of lesions in the arteries and heart by means of a massive injection of horse serum was demonstrated in the classical observations of Rich. Confirmation and extension of these studies by many others soon followed, and the lesions so produced were found to be quite similar (if not identical) to those found in *polyarteritis* in man. The lesions consisted of classical necrotizing arteritis, with fibrinoid degeneration involving all coats of the arteries and arterioles, round cell and eosinophilic infiltration, granulomatous changes, and nodules similar to Aschoff bodies in the myocardium These lesions were thus firmly placed in the category of hyperergic reactions, and many examples due to serum disease or hypersensitivity to drugs were thought to be due to a similar mechanism in man. It is of some interest that a selectivity for the heart vessels could be demonstrated by Hawn and Janeway, who found that injections of bovine serum albumin into rabbits induced cardiac lesions predominantly. Injections of bovine serum gamma globulin, on the other hand, resulted in kidney lesions. Whether large doses of foreign protein are used, as shown by Rich and Gregory,

or bacterial cytoplasm or toxoid, recently used by Cohen, arteritis of one description or another can be produced

It had been postulated that glomerulonephritis and rheumatic carditis were due to the results of antigen-antibody combination (Cavelti). Using a collodion particle method and emulsions of human heart muscle or kidney as antigen, the Cavelts claim to show antigen-antibody combination in vitro, using serum from cases of rheumatic fever or glomerulonephritis The test was negative when normal serums were used This work, however, could not be confirmed by others at the time. On the other hand, by using a different technique, Stefanini was able to demonstrate the presence of antibody for human blood vessels in the serums of patients with periarteritis He used fresh aorta and large arteries obtained from stillborn children as the antigen When an extract of these was added to the serum of patients with polyarteritis, a precipitate formed On the basis of these observations, it was postulated that, in patients with vasculitis, an initial change in some part of the vascular tree arises, with the result that some component is regarded as foreign This is then dealt with by the body as is any other foreign protein, with the subsequent production of antibody specific for blood vessels The antibody then combines with the blood vessels, producing the typical lesions

Based on the fact that antibody is in almost all cases an immunologically altered gamma globulin, an attempt was made to demonstrate the existence of gamma globulin itself in the lesions of the various types of so-called *collagen disease* An antiserum to human gamma globulin was made by injecting the latter into rabbits This rabbit antihuman gamma globulin was then labeled with fluorescein by the Coons technique so that it could be visualized in ultraviolet light When this labeled serum was allowed to come into contact with sections of tissue from cases of polyarteritis, disseminated lupus, or of the heart from cases of rheumatic fever, gamma globulin could be shown to exist in the lesions by the marked fluorescence indicating that the tagged antihuman gamma globulin had combined with the human gamma globulin in the tissue Normal tissues did not show this reaction

All these findings then, while they support the theory of hyperergic activity, leave several unanswered questions. The presence of gamma globulin in the lesions of fibrinoid degeneration or arteritis implies that the gamma globulin either contains, or is in essence, the antibody specific for the tissue involved. This has as yet not been demonstrated directly. It is remotely possible, for example, that the gamma globulin is precipitated in these lesions for reasons other than an immune process.

From the foregoing, it seems clear that there must be at least two distinct types of antibody which, by forming antigen-antibody complexes, may involve the cardiovascular system. *The first is dependent on the effects of such a complex derived from some outside source, such as common allergens (foods, pollens, drugs, or serum) combining with the specific antibody involved, or that which occurs following the injection of a foreign serum.* Under these circumstances, elements of the vascular system may be termed the shock organ In the case of foreign serum injection in the experimental animal, Germuth has shown that the lesions form rapidly during the period of antigen excess and before the production of antibody. As the latter forms, some of the lesions begin to regress However, the exact mode by which arteritis, myocarditis, as well as Aschoff-nodule-like lesions are formed is not clear It has been shown that smooth muscle and capillary endothelium play a prominent role. There may thus occur vasoconstriction of arterioles, slowing of the circulation, and a tendency for leucocytes to adhere to the endothelium with migration through endothelial walls. Local edema may also occur According to Germuth, some lesions are due to the actual intravascular precipitation of antibody with antigen. However, by whatever means the various structures of the heart and vessels are affected, the situation is in a sense nonspecific, since lesions may arise as the result of many foreign antigens. The *Arthus phenomenon* is in a similar category. Reference to the *Shwartzman phenomenon* is made only to state that while this reaction is extremely interesting, there is little to support the contention that it depends on the formation of antibody, or on other immune mechanisms.

The second means by which lesions of the

cardiovascular system may arise on an immune basis is predicated on the formation of "autoantibodies." *This postulates that the actual tissue involved, some component of heart muscle or its connective tissue, for example, behaves as an antigen.* Thus, antibody formed as a result selectively seeks out the original tissue responsible. That such a possibility might exist was for years an unacceptable concept and was referred to as "horror autotoxicus" by Ehrlich. However, as newer evidence has accumulated, this type of response is providing an explanation for the lesions of a growing number of disease entities. Thus, Dameshek has recently reviewed the immune mechanisms relating to disseminated lupus erythematosus, and a similar discussion was presented by the author. Using the tissue of an animal, and some medium such as Freunds adjuvant, which contains mineral oil and killed tubercle bacilli, it is possible to induce lesions in the same species (or indeed, in some cases, in the animal from which the tissue was originally removed). Depending on the type of tissue used, one can induce lesions of the central nervous system of a demyelinating nature, thyroiditis, aspermatogenesis, ophthalmitis, or glomerulitis.

In man, one of the enigmas which exists is how such autoantibodies may actually arise. There are at least four possibilities:

1. Taking *rheumatic fever* as an example of an "allergic" or "hyperergic" disease, it is established that the cardiac manifestations appear in 2 to 6 weeks after the initial streptococcal infection. This is regarded by some as the period of sensitization. The streptococcus gives rise to the formation of antibody which, in the normal individual, combines with the organism (or some part of it) and ultimately rids the body of the invading organisms This combination of antigen (bacterium) with its specific antibody might induce lesions in the same manner that antibody to foreign serum might do as it combines with the antigen, in the manner described above.

2. Another possibility is that the organism invades the heart muscle or blood vessels, forming a small nidus of infection which might be dealt with as would any other local infection, ultimately leaving a tiny scar However, the tissue involved might, in a suitable patient, be regarded as foreign, since it is now altered by the infective process. If there was sufficient similarity between the altered tissue and normal heart muscle, the antibody so formed might be directed against both with the consequent production of lesions. Such a possibility does not seem likely.

3. A third means by which autoantibody might arise depends on the structural similarity between the mucopolysaccharides of tissues and those found in bacterial antigens With antibodies formed to combat the latter following infection, they would have an affinity for not only the streptococcus but certain elements of heart tissue or blood vessel as well. Consequently, lesions might again be the result of a complex formed between antibody and cardiac tissue. Such a possibility is quite logical in the light of work concerning the *mucopolysaccharides*, and could also explain the selectivity of patients For example, it is probable that there is a difference in the mucopolysaccharides of certain tissues, such as heart or blood vessels, of those individuals who are prone to attacks of rheumatic fever, as compared to those who do not develop this disease.

4. In terms of certain work, particularly that of Roitt, who has shown clearly that antibody to thyroglobulin is present in the serum of patients with *Hashimoto's disease (thyroiditis)*, it is conceivable that a similar mechanism may prevail in the production of lesions in other tissues of the body. Apparently, certain tissue complexes, of which thyroglobin is an example, are "foreign" to the body of the individual or animal in which they reside This implies that, under normal circumstances, thyroglobulin is retained within the thyroid capsule during the entire lifetime of the individual. As such, it does not circulate Should it for some reason escape into the circulation, it is treated as a foreign protein, and stimulates antibody production. This antibody has a specificity for thyroglobulin and returns to the thyroid, forming a complex with thyroglobulin and further damaging the tissue. It is not known how the original lesion begins, but clearly this disease must depend upon some alteration in the metabolism of the individual concerned, otherwise one might expect the condition to appear much more frequently, for example after operative procedures to this gland. However, this is a characteristic of allergic disease in general. Such a mechanism

as has been demonstrated in the case of the thyroid could quite conceivably explain lesions in other parenchymal tissues, such as heart or blood vessels

One of the tenets of all allergic mechanisms is the demonstration of antibody. In the case of thyroiditis, the addition of thyroglobulin to the serum of a patient with this disease results in a precipitin reaction due to the antigen-antibody complex so formed It has not been possible to demonstrate the presence of antibody to any of the elements of the heart, such as pericardium, myocardium, or blood vasculature with the exception of the work of Stefanini, and this has not yet been confirmed

In summarizing the data in a general way, therefore, it would seem that a particular type of individual, with some metabolic deviation, is first necessary Such an individual is prone to develop antibodies to a whole host of factors which do not arise in the nonallergic subject These include not only foods, pollens, and drugs but also bacteria In terms of the latter, it is entirely possible that, not only are the conventional types of antibodies produced but possibly others which would not arise following infection in a nonallergic subject. It also seems possible that the allergic individual may possess mucopolysaccharides which more closely resemble those of the bacterial antigens in general, than do those of the so-called "nonallergic" subjects The final possibility of autoantibodies has already been speculated on

CLINICAL ENTITIES

Although these will be dealt with more fully in other sections of this book, they are now briefly reviewed in relation to the mechanisms of allergy which are involved

Tachycardia and Arrythmias Cases of paroxysmal tachycardia, extrasystoles, or atrial fibrillation due to allergy to foods have been reported by Kern and Harkavy, as well as others In all of the cases reported, other forms of common allergy were associated, and there were no other diseases, such as rheumatic fever or myocarditis to account for the cardiac symptoms Avoidance of foods by trial and error rather than by skin testing resulted in a disappearance of symptoms These cases are not common in the literature but undoubtedly exist.

Coronary Heart Disease. Reports of attacks of precordial pain due to food hypersensitivity are rare, and it is unlikely (in view of the paucity of such cases) that such a mechanism exists There have been cases in which the administration of a drug (such as aspirin) was associated with severe precordial pain and urticaria In one of these cases, ECG abnormalities, consisting of prolongation of the P-R interval and notching of S_2 and S_3 waves with inversion of T_3 wave, could be induced by the administration of 5 grains of aspirin. These changes disappeared with the cessation of the attack Again, the incidence of such reports in the literature is exceedingly small and, as a result, such cases must either be rare or missed clinically.

Rheumatic Fever and Rheumatic Myocarditis. This is by far the most common form of bacterial allergy giving rise to hyperergic lesions of the cardiovascular system (see Part 7) The disease is characterized by pancarditis, chorea, subcutaneous nodules, erythema marginatum, and polyarteritis. Although it is rare in infancy and old age, cases have been described The organism involved is the *streptococcus* Until recently, it was impossible to isolate organisms from the circulation or serous effusions during the active stages of the disease, but this has been accomplished by means of refined techniques Nevertheless, the incidence of the condition in relation to streptococcal infection, an incubation period varying from 4 to 6 weeks, evidence of previous infection such as the antistreptolysin titer, and antibody capable of agglutinating hemolytic streptococci in high titer, all support the theory that this is an allergic disease

Bacterial Sensitivity, Myocarditis, Pericarditis, and Arteritis. There exists a group of patients, characterized by an allergic background or hereditary trait, in whom mild symptoms such as a sinusitis with vasomotor rhinitis are the first to appear. This soon progresses to asthma, related to the infection, which in turn becomes worse, and is complicated by weight loss and a feeling of malaise As time progresses, pulmonary infiltrations of an evanescent character may be observed by serial x-ray examinations, these are characteristic of so-called *Loeffler's syndrome* or transient pulmonary eosinophilia At the same time, with or without renal involvement, there are myocardial changes with cardiac enlargement, and ECG changes. Some of these patients pro-

gress to a full-blown picture of *periarteritis nodosa*, with fluctuating eosinophilia, fever, muscle pain, and marked debility. Lesions at autopsy consist of a widespread vasculitis including the coronary vessels. Clinically, several forms are recognized, according to Zeek and to Banks.

Various Lesions. It has been postulated that the endocarditis, pericarditis, and arteritis of *disseminated lupus erythematosus*, the vascular lesions of *Wegener's granulomatosis*, as well as such diverse entities as *subendothelial fibroclastosis* and *Fiedler's myocarditis*, could be due to autoantibody formation. These entities, as well as the various types of myocarditis secondary to viral infection, might be due to such mechanisms but there is as yet no direct proof or evidence to support this contention. Finally, many descriptions of so-called "allergic vasculitis," with lesions of blood vessels due to sensitivity to diverse agents, have been reported by McCombs et al. and by Harkavy. In some patients, withdrawal of the offending agent or administration of steroids resulted in a disappearance of the lesions. The fact that the majority of these hypersensitivity diseases are associated with an elevation of the gamma globulin fraction of the plasma proteins is taken as indirect evidence of abnormal antibody production.

Cardiovascular Manifestations of Collagen Diseases

MATTHEW TAUBENHAUS AND BERNARD EISENSTEIN

The Heart in Lupus Erythematosus; the Heart in Libman-Sacks Disease

EUGENE LIPPSCHUTZ

CARDIOVASCULAR MANIFESTATIONS OF COLLAGEN DISEASES

The involvement of the cardiovascular system by the pathological processes commonly described as *collagen diseases* is extensive and constitutes an important feature in the diagnosis and differentiation of these entities Despite this, the affections of the heart and vessels may not be apparent to the clinician for a long time, and manifestations of disorders of other organs or organ systems may be in the foreground The validity of the general term collagen diseases has been discussed (Taubenhaus et al). It has been pointed out that reference to the word "collagen" in regard to pathological processes meant a step forward in recognizing a common denominator of these diseases As the physiology of connective tissues was studied more extensively (Meyer, Dorfman; Randall), and the complex interdependence of its various structures was recognized, it was generally felt that the term "collagen diseases" *is not* appropriate because the cells and other fibers, as well as the ground substance, participate in the pathological reactions Moreover, in some syndromes, the striated muscle is primarily and predominantly involved Klemperer (1957) has clarified some points concerning the general terminology.

Cardiovascular manifestations of systemic lupus erythematosus, necrotizing angiitis, progressive systemic sclerosis (scleroderma), dermatomyositis, and serum sickness will be briefly described below The role of certain steroids, which have played an important part in the study of these diseases will also be discussed Rheumatic fever and rheumatoid arthritis, which in many ways fall into the same category, will be omitted. However, it is noteworthy that types of carditis and aortitis have been described in rheumatoid arthritis which differ histologically from the ones found in rheumatic fever (Sinclair and Cruickshank).

It may be stated here that great similarities exist in many of these disorders Fibrinoid degeneration, occasional platelet thrombi, involvement of the small vascular bed, nonspecific inflammatory reactions, and other lesions occur in most of these diseases and it may be difficult for the pathologist to separate clearly the various entities The opinion has been expressed by Beigelman et al that these diseases vary only in the degree of the associated tissue reactions. However, clinically, most of these conditions stand out as more or less definite diseases.

An entirely different group of connective tissue diseases with involvement of the cardiovascular system must be separated from the conditions under present discussion: they are heritable and not inflammatory, and, in particular, no fibrinoid necrosis occurs. These entities (Marfan syndrome, Ehler-Danlos syndrome, etc.) have been reviewed by McKusick (1956).

Considering the origin of collagen diseases in general, the question arises as to whether they can be classified as manifestations of

allergic reactions. In the past, fibrinoid degeneration was thought to be the morphological substrate of an antigen-antibody reaction More recently, it has been pointed out that *fibrinoid degeneration* is not exclusively limited to allergic reactions or diseases. There is even a question as to whether the fibrinoid degeneration is identical in the various diseases. Certain variations of the staining characteristics seemed to point to a variety of materials which constitute the substrate for this histological picture. Plasma fibrinogen forms an important part of fibrinoid.

The histology of allergic reactions has been extensively studied, and indeed certain analogies have been found with the pathology of collagen diseases. The changes can be ascribed to an antibody-antigen reaction and usually begin within the vascular bed. Initially, there is an alteration of the blood flow through capillaries with adherence of leucocytes and platelets to the vessel wall, and increased capillary permeability Antibody molecules (labeled with fluorescent tags) can be seen accumulating in the perivascular spaces around the small arteries Necrosis and secondary inflammation follow, and constitute the experimental *allergic angiitis.*

Electron-microscope studies of the affected collagen tissues, following an Arthus phenomenon, reveal changes in the fibers. Some diseases, such as serum sickness and certain types of necrotizing angiitis, have most likely an allergic pathogenesis and represent the clinical counterpart of the experimentally induced allergic processes In *systemic lupus erythematosus,* certain features point to active immune-biological reactions Serum obtained from patients with this disease is capable of inducing specific morphological changes in the nuclei of polymorphonuclear leucocytes in vitro. A gamma globulin which has a specific affinity for isolated cell nuclei and nuclear nucleoprotein is the responsible serum factor Fluorescent antibody technique has demonstrated the localization of the globulin on cell nuclei during this reaction (Holman and Kunkel; Friou) Of interest has been the production of a syndrome similar to systemic lupus erythematosus, with the appearance of L.E. cells, caused by prolonged administration of hydralazine In rheumatoid arthritis, dermatomyositis, or progressive systemic sclerosis, there is no evidence of allergic etiology. One of the outstanding features, which particularly distinguish the latter collagen diseases from the true, usually self-limited, allergic reactions, is their perpetuation and self-maintenance over a period of years. The reason for this phenomenon is completely obscure.

SYSTEMIC LUPUS ERYTHEMATOSUS (S.L.E.)

The knowledge of this disease has been considerably enriched by the attempt to recognize its pathophysiology (Klemperer, 1955) and the discovery of the L.E. phenomenon (Hargraves, Haserick). The diagnosis can now be made early and the course of the disease studied over a period of years The signs and symptoms may be protean, and years may elapse before cardiovascular involvement becomes clinically manifest. Vascular involvement may exist even in early stages and can be recognized by biopsies of the skin, liver (Dubois, 1952), the kidneys (Muehrke et al), and, rarely, the skeletal muscle The pathological studies of the cardiovascular manifestations show certain characteristics which facilitate the diagnosis and explain some of the functional impairment In the medium-sized and smaller vessels there is a subendothelial fibrinoid necrosis of the vascular wall which may involve the entire thickness of the vessel Actual occlusion of the lumen by thrombosis is rare, but swelling of the vessel wall may cause narrowing of the lumen and impaired blood flow. Fibroblastic proliferation occurs but it is quite characteristic that the inflammatory reaction in and around the necrotic portions is minimal. Hemorrhagic diathesis is common, due to the vascular lesions, in addition to the coagulation defects and the thrombocytopenia commonly associated with this disease. In the spleen the lesions are commonly found in the penicillary arteries and are characterized by periarterial fibrosis. Serial renal biopsies have demonstrated that the characteristic *wire loop lesions,* described in the glomerular tufts, probably represent only one stage in the development of the complex lupus nephritis (Muehrke et al).

Involvement of the *heart* itself is usual. Pericardial effusions, fibrinoid degeneration of the pericardium, and epicardial hemorrhages are common. The myocardial lesions are charac-

terized by the typical involvement of the smaller branches of the coronary arteries with focal necrosis of the heart muscle. Diffuse exudative changes compatible with a myocarditis or local fibrinoid degeneration of the interstitial tissue can also be observed. The endocardial lesions consist of swellings of the valves, due to fibrinoid degeneration, with formation of *verrucae* These occur on both sides of the cusps and, in addition, are found on the mural endocardium and in the valve pockets Hematoxylin bodies are characteristically found in the valves, but are also seen in other organs.

The clinical manifestations of S L.E. caused by cardiovascular involvement are protean *Raynaud's phenomenon* occurs quite frequently. Central nervous system involvement due to lupus arteritis has been observed repeatedly. Convulsions or hemiplegia may initiate a more generalized symptomatology in some cases. Peripheral neuritis has been observed and may make the differentiation from periarteritis nodosa difficult. Retinal hemorrhages, exudates, perivasculitis (cytoid bodies), embolic petechiae, and occasional arterial occlusion may be found on fundoscopy (Hollenhorst and Henderson) Gastrointestinal hemorrhages and pancreatitis due to lupus *angiitis* have been observed Occasional lupus angiitis can be found in the liver, but the hepatomegaly encountered in this disease is mainly due to parenchymal changes Urinary findings, varying from microscopic hematuria to heavy albuminuria accompanied by hypertension or the nephrotic syndrome may be encountered, depending on the stage and the degree of the renal vascular involvement *Hypertension* due to lupus nephritis is usually seen when renal involvement is sufficient to lead to azotemia Roentgenographic changes in the lung suggesting pneumonitis may be specific and related to the vascular disease (Baggenstoss). Lesions of the *coronary arteries* may give rise to an anginal syndrome or even myocardial infarction *Pericarditis,* with all its signs and symptoms is one of the most common occurrences and can be observed in nearly 50 per cent of the cases *Pericardial effusion* may be prominent and occasionally require repeated paracentesis Endocarditis, widely known since its description by Libman and Sacks (Gross) is commonly encountered in the necropsy material Clinically, it is usually silent. Systolic murmurs are frequently heard but difficult to evaluate because of fever, tachycardia, and anemia which are present in most cases Diastolic murmurs in the mitral and aortic region can be heard and are probably due to verrucous endocarditis. Bacterial endocarditis may be engrafted on these verrucae. Cardiac enlargement is frequent and related to the myocardial involvement. Congestive failure is common The electrocardiogram reflects the underlying pathologic process occurring in the pericardium and myocardium Accordingly, the most typical changes are those indicating diffuse pericarditis. Transient T-wave flattening and inversion in various leads associated with intermittent prolongation of the P-R interval would reflect multiple focal areas of myocarditis In some cases, where confluent necrosis is present, classical infarct patterns may be observed (Taubenhaus et al.).

NECROTIZING ANGIITIS

Necrotizing angiitis is characterized by a systemic involvement of the vascular tree and most of the manifestations of this condition are attributable to the vasculitis In general, the characteristic lesion consists of disseminated areas of focal or segmental *fibrinoid necrosis involving all* three layers of the arterial and venous walls It is accompanied by a pronounced inflammatory reaction, which, depending on the stage and type of the disease, may exhibit polymorphonuclear leucocytes, round cells, eosinophils and giant cells in varying amounts The inflammatory exudate may extend beyond the adventitia and surround the vessels like a cuff. Thrombosis of vessels and *fibrosis* in later stages is characteristic. Due to the loss of continuity of the structure of the vascular wall, *microaneurysms* form, and rupture of the vessels with perivascular hemorrhage may occur

A considerable amount of experimental work has been done to elucidate the causes of the vascular lesions Some investigators interpreted them as the pathological substrate of *antibody-antigen reactions,* in which circulating globulins deposited in and around the vascular wall play a major part (Ehrlich). In certain types of angiitis (see below) the antigenic origin may very well be applied, although in others no such evidence exists Hypertension may be

a factor under special circumstances. In human beings, hormonal factors (Selye 1951), in particular the mineralocorticoids, have not been proved to be of etiological significance.

An attempt has been made to outline various entities within the syndrome on the basis of certain etiological, pathological, and clinical aspects. The following four groups of primary angiitis have been characterized: (1) hypersensitivity angiitis; (2) allergic granulomatous angiitis; (3) periarteritis nodosa; and (4) temporal arteritis. These subdivisions, although helpful, are not entirely satisfactory, as frequent overlapping occurs, and cases which may not fall into any of these categories are frequently observed.

Hypersensitivity angiitis (Zeek; see Chap. 2) may occur in response to parenteral administration of foreign proteins and certain drugs (sulfonamides, iodine, Dilantin, and propylthiouracil). It is probably the clinical counterpart of vascular lesion produced experimentally (Rich and Gregory) Small arteries, venules and precapillaries are involved. All the lesions appear to be of the same age. The most common sites of involvement are the kidneys, cardiac muscle, lungs, and spleen. Necrotizing glomerulitis is quite common. The diagnosis is often difficult because of the underlying disease, for which the drugs were administered The course is rapid and frequently fatal Fever is always present and the skin is commonly affected by petechiae and urticarial eruptions. Cardiac manifestations, such as congestive failure, occur and may be due to multiple miliary infarcted areas in the myocardium. Nephritis with hematuria and azotemia is prominent The pulmonary involvement can be observed roentgenologically and may appear as areas of pneumonitis Splenomegaly may be seen. The manifestations described above are encountered in the most severe cases, little is known about milder forms, which are transient and heal without permanent damage to the organ function. Such reversible states, in which the diagnosis was established by biopsy, have been described by McCombs et al. Transitions from such mild forms to the more severe ones are probably common

Allergic granulomatous angiitis (Churg and Strauss) involves smaller arteries in various organs causing vascular occlusion and infarction. It is associated with asthma, fever, and eosinophilia. This disease is characterized by abundant eosinophilic reaction in and around the necrotic vessels and also by extravascular granulomas exhibiting fibrinoid necrosis, eosinophilia, and giant cells. The distribution is similar to that of hypersensitivity angiitis except that the lesions are at different stages of development indicating their varying age Involvement of the mesenteric vessels with formation of aneurysms is common Clinically, multiple organ systems are involved. Cerebral and peripheral nerve manifestations and renal involvement are prominent. Death occurs, usually due to uremia, cardiac failure, or cerebral hemorrhage. A separate entity has been outlined by Wegener (Fahey et al) which is similar to the allergic granulomatous type, except that severe inflammatory and necrotizing disease of the paranasal sinuses is coexistent. Possibly also cases associated with eosinophilic pneumonia and enormous leucocytosis have a similar pathogenesis. In the latter, the renal vascular involvement may not be prominent (Engfeld and Zetterstrom).

Periarteritis nodosa is the most common type of necrotizing angiitis Its cause is unknown The small as well as the medium-sized arteries or veins may be involved. Foci are found in the renal, coronary, mesenteric, and muscular arteries; the splenic and the pulmonary vessels are usually spared. *Microaneurysm* formation is common. Histological evidence of myocardial necrosis is common, although the coronary arteries may be involved without clinical evidence of myocardial infarction (Sinclair and Nitsch). The papillary muscle may rupture due to infarction. Renal infarcts are quite common and necrosis in any organ may occur due to ischemia. The disseminated involvement in various organs gives rise to the protean manifestations of periarteritis nodosa Ulcerations of the skin, focal necrosis of the skeletal muscles with pain and tenderness, are not unusual Peripheral neuritis and cerebral vascular accidents are common. Gastrointestinal bleeding and hepatic involvement has been observed (Mowrey and Lundberg). Cardiac hypertrophy and dilatation with congestive failure and retinopathy may be partially secondary to renal involvement and hypertension. Congestive failure is the most common cause of death, followed in frequency by

uremia and "stroke" Serial electrocardiographic tracings may, depending on the cardiac involvement, show more or less typical evolution of pericarditis, myocarditis, or myocardial necrosis More commonly, nonspecific ST-T and P-R changes are seen When hypertension and renal disease are the predominant manifestations, evidence of left heart strain or electrolyte disturbance may appear

Temporal arteritis, as described by Horton, is usually confined to the cranial arteries, although involvement of other vessels such as the coronaries, the aorta or the larger muscular arteries may be observed on occasion (Cooke et al, Morrison and Abitbol). Its pathogenesis is also unknown and again little evidence exists that allergic or hypersensitivity factors play a role Fibrinoid necrosis of the vascular wall with inflammatory, granulomatous nodules is prominent. These are characterized by the presence of large amounts of giant cells It occurs in elderly patients and the course is usually self-limited Blindness or cerebral involvement is common and the latter may result in death.

Necrotizing angiitis may also occur in association with well-defined diseases as part of the original process

Arteritis may occur in association with rheumatic fever and carditis (*rheumatic arteritis*). The small arteries and veins are involved, mainly in the myocardium and the lungs, and occasionally in the mesenteric region In any case of severe rheumatic fever, abdominal pain, renal and central nervous system involvement should lead to the consideration of a disseminated arteritis (Friedberg and Gross, 1934)

In malignant hypertension, *necrotizing arterial* [illegible] and Knowles) have found a *significant* incidence of periarteritis at necropsy in such cases Severe hypertension of the pulmonary circulation such as seen in *Eisenmenger's* syndrome (Zeek) may be associated with angiitis localized to the pulmonary *vessels* This would indicate the causative role of hypertension in a small group of cases of necrotizing *angiitis*

In all diseases of the connective tissues, angiitis may under certain circumstances exhibit an inflammatory character and resemble periarteritis nodosa Angiitis has also been described in granulomatous diseases such as Boeck's sarcoidosis (Jackson and Kass).

PROGRESSIVE SYSTEMIC SCLEROSIS (P.S.S.)

Cardiovascular involvement in P.S S. dominates the clinical picture in many cases and represents, next to the involvement of the skin, esophagus, and lungs, the most important manifestation of this disease. The histological changes occurring in the arterioles consist of thickening of the vascular walls, mainly due to adventitial fibrosis and infiltration with round cells. Proliferation of the intima is frequent and may lead to obstruction of the vessel Any artery in the body may be affected by these or similar changes, *although* the smaller arteries are involved most frequently. Along with the typical changes of the collagen bundles and the fragmentation of the elastic fibers, the vascular changes are the criterion for the histological diagnosis in biopsy material The abundance and thickening of the collagen fibers in various organs, particularly the skin, has no direct relationship to the narrowing of the vascular bed and cannot be regarded therefore as a result of ischemia Only in the kidney is there a characteristic pattern of vascular involvement (Moore and Sheehan). Here the initial lesion consists of thickening of the intima of the interlobular arteries with or without fibrinoid necrosis of the distal interlobular arteries and the afferent arterioles. Depending on the severity of these changes, the next stage may be atrophy of the renal cortex, fibrosis of the glomeruli, and even ischemic necrosis Some question has arisen whether steroid therapy in this condition may not be responsible for such renal changes.

A vascular involvement is also prominent in the clinical syndrome of P S S Raynaud's phenomenon occurs frequently and may be one of the early signs of this disease. In far-advanced cases, trophic changes of the finger tips with ulcerations may be observed

Multiple *factors* combine to result in an impairment of the pulmonary function Bronchiolar involvement, *as well* as a decrease of mobility of the chest and the diaphragm, may severely *impair* pulmonary function, leading to hypoxia and hypercapnea. In addition, vascular obliteration leads to a reduced pulmonary vascular *bed*, giving rise to pulmonary

hypertension. Other factors, such as spotty compensatory emphysema and endobronchial infection due to bronchial obstruction, further impair the physiological processes. All these changes cause a severe strain upon the right heart and may be followed by cor pulmonale.

Cardiac involvement in progressive systemic sclerosis was first adequately studied by Weiss et al and, since then, has been widely recognized (Beigelman et al; Goetz). The weight of the heart is usually increased. Hypertrophy and dilatation of the right heart is common and related to the pulmonary lesions

Pleural and pericardial thickening is frequent. The myocardial changes consist of patchy fibrosis, occasionally secondary to local ischemia due to the vascular lesions, but more frequently independent of the vascular involvement. The interstitial changes may be observed in various stages from early hyperemia and young connective tissue to actual fibrosis. Muscle fibers are destroyed and replaced by interstitial fibrosis (*scleroderma heart*)

Clinical manifestations of the cardiac involvement will vary depending on the extent of the myocardial involvement and the pulmonary disease In cases in which the myocardial involvement is extensive, congestive failure may be the outstanding manifestation and, in certain cases, precede the skin involvement. More localized or less extensive lesions may lead to disturbances in the electrical conduction, and the abnormal electrocardiogram may be the only sign of heart disease The pulmonary disease may impose a severe strain upon the right heart and the full picture of chronic cor pulmonale is quite frequently encountered in P S S Death may ensue from right heart failure The evaluation of the role of right heart failure in causing cyanosis, dyspnea, and rales, may be difficult because of the simultaneous pulmonary involvement Pleural and pericardial effusion may be on the basis of pleuritis and pericarditis, which, however, is rare in P S S. Dependent edema is quite common and may exist without congestive failure Auscultatory findings are not characteristic· accentuation of the 2d pulmonic sound, systolic murmur, gallop rhythm, poor quality of both heart sounds, or decreased intensity of the 1st sound may be encountered. Cardiac catheterization may reveal an elevated pulmonary artery pressure (Austrian et al.).

Enlargement of the pulmonary artery and right ventricle has been demonstrated by means of angiography. When examined roentgenologically, the heart may show a triangular shape with poor pulsations, resembling the findings in pericardial effusion, although pericardiocentesis yields no fluid, and cardiac enlargement is not uncommon. The electrocardiographic alterations in P S S will depend upon the extent and location of the myocardial lesions as well as the degree of pulmonary hypertension. There may be only nonspecific ST-T alterations or prolongation of the AV and intraventricular conduction time due to focal fibrosis in the myocardium The intraventricular block is usually right-sided Low voltage and arrhythmias such as atrial fibrillation and flutter have been described In advanced cases with extensive replacement of the myocardium by connective tissue (Beigelman et al.), patterns of left heart strain and of myocardial infarction may be encountered

The clinical picture of the "scleroderma kidney" is well explained by the vascular changes described above and is characterized by albuminuria, hematuria, and cylindruria The blood pressure rises within a short period of time and azotemia becomes apparent Such changes are usually late manifestations of the disease

DERMATOMYOSITIS

The clinical syndrome of dermatomyositis is dominated by the involvement of the skin and skeletal musculature. The usual onset is characterized by various forms of dermatitis, cutaneous edema, and muscle tenderness which may progress to severe atrophy and weakness, even simulating muscular dystrophy. Fever is frequently present but there are no characteristic hematologic or biochemical findings present. Urinary abnormalities are uncommon and nonspecific. An interesting fact is the high incidence of malignant neoplasms associated with dermatomyositis (Curtis et al.).

The primary pathological process is one of degeneration of muscle fibers, but there may be varying amounts of inflammatory reaction Vascular changes consist of fibrinoid necrosis and deposition of hyalinized material in the media of arterioles, as well as occasional platelet thrombi (Pagel et al.). Inflammatory reactions of the vessels are scanty but occlusions have occurred. These changes have been described in arterioles of small caliber in the

striated muscles, myocardium, and submucosal vessels of the intestinal tract (Wainger and Lever). Some of the latter have been described as being associated with necrosis and hemorrhage. Histologic alterations have been described in all elements of the myocardium Muscle fibers show fragmentation, loss of striation, and vacuolization The interstitial tissue shows swelling, edema, and occasional inflammatory infiltrates. The myocardial changes resemble those seen in the skeletal muscles but are less severe Pericarditis is rare and Aschoff's nodules are not seen

Clinically, the most prominent vascular manifestation is that of *Raynaud's phenomenon*, which may be seen in 10 to 25 per cent of cases, its presence indicates that functional as well as pathological changes are present Nephropathy and secondary hypertension are uncommon, serositis is unusual

Despite the frequency of histologic changes in the myocardium, major clinical manifestations of cardiac involvement are not prominent Findings such as tachycardia disproportionate to temperature elevation, and electrocardiographic alterations (S-T depressions and flat or inverted T waves in various leads) are common However, congestive failure, though reported, is uncommon Cardiomegaly is not common, although O'Leary and Waisman noted five instances in their series. Arrhythmias, such as auricular fibrillation and tachycardia and SA and AV block, have been observed on occasion A blowing systolic murmur may be heard in the absence of valvulitis Dyspnea is usually due to involvement of the respiratory muscles. The usual cause of death is pneumonia or respiratory failure secondary to the involvement of the muscles of deglutition and respiration Some of the aspects of this condition were recently reviewed by Domzalski and Morgan.

THE SERUM SICKNESS SYNDROME

A great deal of experimental work has been concerned with the pathologic changes occurring after injection of foreign protein, and much of our knowledge of the behavior of the cardiovascular system under such conditions has been gained from these experiments The application of this knowledge to clinical medicine, as reviewed by Ehrich, has yielded important contributions to our understanding of the serum sickness syndrome Moreover, conclusions have been drawn from such experiments in regard to collagen diseases in general The significance of antigen-antibody reactions in the production of cardiovascular changes and the hyperglobulinemia associated with these conditions have been intensely studied. Still, the gap between the acute serum-sickness type of syndrome and the self-maintained, chronic "collagen" disease remains to be filled.

The serum sickness syndrome can become manifest, not only after parenteral administration of proteins, but also after administration of smaller molecules (such as penicillin) by mouth It occurs after a latent period, probably necessary for the formation and deposition of antigen-antibody reactors in the tissues. Urticaria, joint swellings, and fever are the most prominent signs The course is self-limited, and healing occurs without residual damage to the tissues in the majority of cases. Death, however, may occur during such severe reactions Pathological studies of autopsied cases reveal extensive lesions involving the smaller vessels and all the cardiac structures. Tissue swelling and edema are seen in the early stages Fibrinoid necrosis of the vascular wall, proliferation of fibroblasts and endothelial cells, as well as infiltration with lymphocytes and plasma cells in all layers of the heart occur. Pericardial and pleural effusions have been described In milder cases, no cardiovascular manifestations may be obvious, except for abnormal capillary permeability as indicated by the urticaria In some instances, changing loud systolic murmurs and cardiac enlargement occur Electrocardiographic abnormalities have been described. They consist mainly of nonspecific ST-T changes. However, a number of instances of young individuals with electrocardiographic evidence of myocardial infarction has been reported. Pericardial friction rubs and electrocardiographic evolution of typical pericarditis have also been described (Contro and Mond)

STEROID THERAPY OF CARDIOVASCULAR COMPLICATIONS IN COLLAGEN DISEASES

Since the introduction of ACTH and the various adrenal steroids and their derivatives into clinical medicine, new avenues of therapy have been opened, and a new, intensive study of the subject from the theoretical and clinical viewpoint, has begun. So far, no proof of an

hypertension. Other factors, such as spotty compensatory emphysema and endobronchial infection due to bronchial obstruction, further impair the physiological processes. All these changes cause a severe strain upon the right heart and may be followed by cor pulmonale.

Cardiac involvement in progressive systemic sclerosis was first adequately studied by Weiss et al. and, since then, has been widely recognized (Beigelman et al.; Goetz). The weight of the heart is usually increased. Hypertrophy and dilatation of the right heart is common and related to the pulmonary lesions.

Pleural and pericardial thickening is frequent The myocardial changes consist of patchy fibrosis, occasionally secondary to local ischemia due to the vascular lesions, but more frequently independent of the vascular involvement The interstitial changes may be observed in various stages from early hyperemia and young connective tissue to actual fibrosis Muscle fibers are destroyed and replaced by interstitial fibrosis (*scleroderma heart*)

Clinical manifestations of the cardiac involvement will vary depending on the extent of the myocardial involvement and the pulmonary disease. In cases in which the myocardial involvement is extensive, congestive failure may be the outstanding manifestation and, in certain cases, precede the skin involvement More localized or less extensive lesions may lead to disturbances in the electrical conduction, and the abnormal electrocardiogram may be the only sign of heart disease. The pulmonary disease may impose a severe strain upon the right heart and the full picture of chronic cor pulmonale is quite frequently encountered in P.S S Death may ensue from right heart failure The evaluation of the role of right heart failure in causing cyanosis, dyspnea, and rales, may be difficult because of the simultaneous pulmonary involvement Pleural and pericardial effusion may be on the basis of pleuritis and pericarditis, which, however, is rare in P.S S. Dependent edema is quite common and may exist without congestive failure Auscultatory findings are not characteristic· accentuation of the 2d pulmonic sound, systolic murmur, gallop rhythm, poor quality of both heart sounds, or decreased intensity of the 1st sound may be encountered. Cardiac catheterization may reveal an elevated pulmonary artery pressure (Austrian et al).

Enlargement of the pulmonary artery and right ventricle has been demonstrated by means of angiography. The usual cause of death is pneumonia or respiratory failure secondary to the involvement of the muscles of deglutition and respiration Some of the aspects of this condition were recently reviewed by Domzalski and Morgan.

THE SERUM SICKNESS SYNDROME

A great deal of experimental work has been concerned with the pathologic changes occurring after injection of foreign protein, and much of our knowledge of the behavior of the cardiovascular system under such conditions has been gained from these experiments The application of this knowledge to clinical medicine, as reviewed by Ehrich, has yielded important contributions to our understanding of the serum sickness syndrome. Moreover, conclusions have been drawn from such experiments in regard to collagen diseases in general The significance of antigen-antibody reactions in the production of cardiovascular changes and the hyperglobulinemia associated with these conditions have been intensely studied. Still, the gap between the acute serum-sickness type of syndrome and the self-maintained, chronic "collagen" disease remains to be filled.

The serum sickness syndrome can become manifest, not only after parenteral administration of proteins, but also after administration of smaller molecules (such as penicillin) by mouth It occurs after a latent period, probably necessary for the formation and deposition of antigen-antibody reactors in the tissues. Urticaria, joint swellings, and fever are the most prominent signs The course is self-limited, and healing occurs without residual damage to the tissues in the majority of cases Death, however, may occur during such severe reactions Pathological studies of autopsied cases reveal extensive lesions involving the smaller vessels and all the cardiac structures. Tissue swelling and edema are seen in the early stages Fibrinoid necrosis of the vascular wall, proliferation of fibroblasts and endothelial cells, as well as infiltration with lymphocytes and plasma cells in all layers of the heart occur Pericardial and pleural effusions have been described. In milder cases, no cardiovascular manifestations may be obvious, except for abnormal capillary permeability as indicated by the urticaria. In some instances, changing loud systolic murmurs and cardiac enlargement occur. Electrocardiographic abnormalities have been described They consist mainly of nonspecific ST-T changes However, a number of instances of young individuals with electrocardiographic evidence of myocardial infarction has been reported Pericardial friction rubs and electrocardiographic evolution of typical pericarditis have also been described (Contro and Mond).

STEROID THERAPY OF CARDIOVASCULAR COMPLICATIONS IN COLLAGEN DISEASES

Since the introduction of ACTH and the various adrenal steroids and their derivatives into clinical medicine, new avenues of therapy have been opened, and a new, intensive study of the subject from the theoretical and clinical viewpoint, has begun. So far, no proof of an

actual cure in any of the disorders is available, although the beneficial results in certain cases are striking.

Steroid therapy improves the patient's subjective sense of well-being. The fever, the joint, skin, mucous membrane, and other manifestations respond dramatically in many cases. The plasma proteins and the hematological manifestations may revert towards normal. The effects of these substances on the actual pathohistology in S.L.E. is poorly understood. Serial renal biopsies do not seem to contribute to our knowledge of the influence of corticoids upon the basic lesion. Autopsies of cases of S.L.E. treated with steroids or ACTH do not seem to reveal any major differences from untreated cases. It must be remembered, though, that clinically well-documented cases of S.L.E., which at autopsy showed none of the pathological changes expected, have been repeatedly described. The endocarditis characteristic of S.L.E. does not seem to be influenced by ACTH or the corticoids. The pericarditis and pericardial effusion may disappear. The influence on the myocarditis may be favorable, with decrease in heart size and subsidence of congestive failure.

Necrotizing angiitis is in general favorably influenced by the administration of ACTH or steroids. Actual healing can be observed histologically but may result in occlusion of vessels, this may lead to serious complications (Shick and Kvale).

Theoretical considerations indicate that corticosteroids have a profound effect upon the function and structure of small blood vessels and could lead to actual angiitis through an obscure mechanism (Taubenhaus et al.). Angiitis may also occur if there is an abrupt withdrawal of corticoids after a period of prolonged therapy (Slocumb et al.)

The cardiovascular manifestations of progressive systemic sclerosis are not significantly influenced by steroid therapy, although some beneficial effects upon the cutaneous manifestations, the esophagus, and to a certain degree the pulmonary lesions has been described (Taubenhaus et al.).

In dermatomyositis there may be a favorable effect upon the general symptom pattern, but insufficient information exists concerning the effect upon cardiovascular manifestations.

Serum sickness is a self-limited disease, the duration and severity of which may be favorably influenced by steroid therapy.

CORTICAL STEROIDS AND COLLAGEN DISEASES

With the demonstration of the effectiveness of adrenal corticoids and ACTH in collagen diseases, two important questions have arisen.

1. Are collagen diseases actually associated with or caused by endocrine disorders, in particular adrenocortical deficiency?

2. What is the mode and mechanism of the action of corticoids?

The answer to the first question is that there is no evidence that endocrine disease is pathogenetically related to collagen diseases. All the endocrine manifestations described can be encountered in any other chronic disease and are related to stress and exhaustion of the endocrine system. Extensive literature has accumulated dealing with the mode of action of anti-inflammatory steroids. In general, it can be said that at least three factors play an important role:

1. An altered vascular reaction to allergic and inflammatory processes resulting in alteration of the course and reduced formation of new capillaries in granulation tissue.

2. A suppression of all the mesenchymal structures playing a major part in inflammatory and allergic conditions. This suppression includes the fibroblasts, ground substance, and collagen fibers, which are all constituents of the tissues affected in collagen diseases.

3. Information has also accumulated that steroids interfere with the formation of antibodies and certain antibody-antigen reaction

THE HEART IN LUPUS ERYTHEMATOSUS; THE HEART IN LIBMAN-SACKS DISEASE

The frequency with which the heart is involved clinically, pathologically, or both, in lupus, is well documented and has been emphasized in several monographs (Talbott; Harvey et al.). A figure of at least 50 per cent would seem conservative.

Historically, the cardiac manifestations were described by Osler (1895), who stressed the

visceral complications including instances involving the heart in particular, and the cardiovascular system in general His original impressions have been analyzed and reevaluated by many others, particularly Tumulty and Harvey, and again by the Reifensteins Libman and Sacks (1924) stressed the endocardial factor and described in detail the pericardial and myocardial involvement. Baehr and Klemperer and Schifrin also reviewed the problem extensively, as have many others

The "rediscovery" (to use Talbott's term) of this interesting syndrome as a collagen disease is probably due to improved methods and techniques of L E cell demonstration and to other diagnostic procedures Dubois (1956) pleads for an awareness of the disease on the grounds that he has seen 175 patients in 6 years in one hospital, an incidence making the entity more common than subacute bacterial endocarditis, leukemia, pernicious anemia, or Hodgkin's disease—at least in that institution

The sex distribution is *predominantly female*, on the order of at least 90 per cent Detailed studies as to causative factors have been focused on physical, chemical, and bacteriologic aspects and, in the last, both tubercular and streptococcic origin have been suggested The relationship to other so-called collagen diseases has been reviewed by Talbott, and the differential diagnosis is concerned with such entities as rheumatoid arthritis, acute rheumatic fever, Raynaud's syndrome, polyarteritis, dermatomyositis, scleroderma, and thrombocytopenic purpura.

PATHOLOGIC CHARACTERISTICS

Lupus is a complex multiorgan-system disease, in which the heart may be extensively involved *Gross* (1940), in his evaluation of data supplied by others, noted nonbacterial, verrucous endocarditis in 55 per cent of the cases, sometimes the plaques are small, often they are large and flat Pericardial involvement occurred in 70 per cent of the cases, either by serous effusion or adhesive pericarditis. Myocardial involvement occurred in 35 per cent, the myocardial process may be intrinsic or due to vascular changes in the coronary system Capillaries, arterioles, and venules are involved and ...

ground substance and collagen fibers has been noted. Subendothelial necrosis may be present, with minimal evidence of overlying endocarditis. Hematoxylin-staining bodies have been found in the cardiac lesions at autopsy.

Dr. Terplan[1] has compiled for the author the gross and microscopic data on three typical cases. It is his feeling, and that of the author's clinical group that there is little evidence to support the theory of relationship to rheumatic lesions, the tissue reactions being of a different nature. On the other hand, there is much to support the theory of embolic phenomena. The author's cases also *emphasize the diffuseness* of the involvement throughout the epicardium, myocardium, and endocardium Three cases studied from the standpoint of gross and microscopic pathology follow.

No. 8591 C.W., 45, April 9, 1954

Gross Examination. The pericardial sac is adherent throughout, by fibrous bands, to the epicardium. The heart is normal in size On section, the myocardium is pale The tricuspid and pulmonic valves are normal, the mitral valve shows marked fibrous thickening A few pinhead-sized elevations are present on the mitral leaflets. The chordae tendineae are markedly thickened, the papillary muscles of the left ventricle show fibrosis. The aortic cusps are fused at the commissures in two areas The valves measure as follows: tricuspid, 11 cm, pulmonic, 7 cm, mitral, 10 5 cm, aortic, 8 cm The right ventricle measures 6 cm in thickness, the left 2 cm. The coronary arteries are patent throughout, with minimal atheromatosis in their walls

Histologic Findings. LEFT ATRIUM. There is a very distinct thickening of the endocardium, with edema and comparatively slight new formation of collagenous fibers There is distinct edema throughout the myocardium with the individual fibers distinctly separated by tissue fluid, there is only minimal activation of histiocytes. Distinct thickening of the en...

... near the surface Some fibrinoid degeneration can also be seen in other parts of the epicardium, especially in the deeper portions close to the myocardium

LEFT VENTRICLE Similar changes appear in the epicardium, with scattered lymphocytes and increase of capillaries. There are also a few fair-

[1] Professor of Pathology, University of Buffalo, School of Medicine

sized histiocytes, but no *Aschoff nodules.* Some fibrinoid change is seen close to the attachment of the heart muscle as well as very conspicuous thickening of the attached valve, with localized edema, pseudocystic liquefaction, and irregular fibrous thickening of the endocardium on the surface of the valve. Other parts are firmly collagenized and show minimal spotty deposits of calcium. There are very prominent fibrocytes, especially around the more edematous pseudocystic areas. The changes described are seen predominantly in the mitral valve

LEFT VENTRICLE AT THE ATTACHMENT OF THE AORTIC LEAFLET There are extensive changes in the epicardium, just as described, with distinct capillarization and edema Also present are typical chronic inflammatory changes, formed largely by histiocytes, a few round cells, edema fluid, and young fibroblasts There is older fibrinoid change in the endocardium of the aortic valve, but only moderate hyalinization. There are rather large areas with granular degeneration of the ground substance, staining somewhat more intensely and slightly purplish with eosin Only scattered proliferating histiocytes are seen at the border of the attached epicardium and myocardium.

RIGHT ATRIUM The most impressive changes are in the epicardium, namely, conspicuous fibrinoid degeneration and rather marked chronic inflammatory reaction together with marked vascularization, edema, and proliferation of histiocytes and fibroblasts, along with a few leucocytes surrounding the fibrinoid precipitations (Fig 16-4). Part of this exudate, in the process of organization, is infiltrated by numerous young fibroblasts, few lymphocytes, and very few leucocytes. These changes are quite extensive. In contrast, there is only minimal edema and slight activation of fibrocytes, with few round cells in the interstitial tissue of the myocardium, which is distinctly edematous. There is slight leucocytic infiltration in a focal distribution in some fibers of the myocardium closer to the endocardium, which also shows edema and activation of fibrocytes.

RIGHT VENTRICLE. This chamber reveals similar changes in the epicardium, with unusually marked edema but more lymphocytic infiltration and activation of histiocytes and young fibroblasts There is distinct extension of this edema and inflammatory reaction into the interstitial tissue of the myocardium, with prominent proliferation of histiocytes, although there is no actual formation of nodular structures. *These infiltrations* show the typical morphology of the so-called *Anitschkow cells* There is, in general, distinct proliferation of fibroblasts between individual myocardial fibers

There are no changes in the *coronary artery,* except for very minimal edema, with slight hyalinization in the inner media. In some areas of the left ventricle, the inflammatory reaction is more conspicuous than in others within the epicardium. Again there is marked activation of both fibroblasts

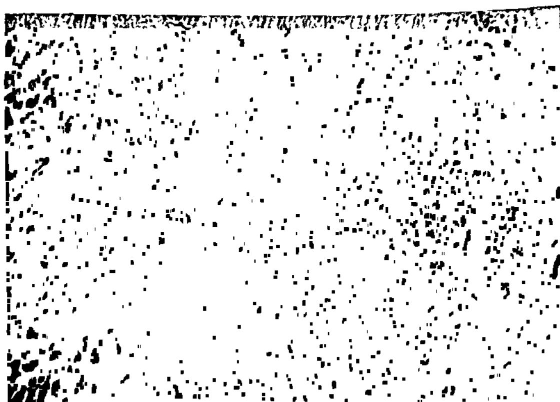

Fig. 16-4. Histologic section of right atrium.

ıd histiocytes in the interstitial tissue of the myo-ardium

The striated musculature showed the most severe hanges of chronic myositis and very marked simi-ır changes in the surrounding fascia and the deep ubcutaneous tissue.

No. 9609 R S, 27, September 17, 1956

Gross Examination. The pericardial sac contains blood-tinged fluid amounting to about 100 ml A delicate film of yellowish-gray fibrinous exudate is seen on the superior anterior surface of the left ventricle, aorta, and pulmonary artery, resulting in an opaque thin sheen covering the epicardium, which otherwise is thin and glistening above the remaining portions of the heart The myocardium of the right ventricle measures 0 4 cm in thickness, the left ventricle, 2 5 cm, the latter shows concentric muscular hypertrophy and fibrotic changes on the posterior wall The trabeculae carneae and papillary muscles are hypertrophied, round, and sturdy, presenting whitish areas of fibrosis, suggestive of embolic phenomena The right ventricle appears dilated with an increased design of moderately prominent trabeculae carneae, suggesting a cor pulmonale The foramen ovale is closed The measurements of the valves are as follows: aortic, 9 cm, pulmonic, 10 cm, mitral, 10 cm, and tricuspid, 12 cm There is an endocarditic change in the mitral valve, characterized by formation of irregular verrucae, giving the gross appearance of *Libman-Sacks disease* The endocarditic vegetations are arranged in conglomerates of mulberry-like masses, localized over the atrial surface of the posterior leaflet, approximately at the margin of the valve attachment The *verrucae* have a tawny yellow color and are of rather soft consistency The aortic valve, also, shows verrucous formations, consisting of a single, beadlike chain along the closing edges, as seen in old remnants of valvular endocarditis.

Histologic Findings MITRAL VALVE. There are very distinct verrucous vegetations, consisting mostly of collagenous fibers. Only close to the surface is there some irregular edema and slight mucoid degeneration Other parts show a very firm, almost entirely hyalinized center Between the small verrucous protrusions, there is older granulation tissue with a few capillaries and localized infiltration by fibroblasts and a few lymphocytes In addition, there are more recent vegetations on the surface, consisting largely of fibrinoid precipitations, firmly adherent and only in the deeper portions partly organized There are a few hemosiderin granular cells close to this area

MYOCARDIUM No inflammatory changes are seen, and there is only slight edema There is distinct hypertrophy of the individual muscle fibers and a few older small fibrous scars, with edema of rather large areas of the original myocardium These changes are present throughout most of the myocardium of the left ventricle Other sections of the left ventricle, particularly of the septum, show extensive older scars in the myocardium, but there is some cellular infiltration along the borders of these scars by histiocytes and fibroblasts, with some *capillarization.*

No 8568 A.B., 66, March 19, 1954 (Case of Cancer)

Gross Examination. The pericardium contains a small amount of straw-colored fluid. The heart is not enlarged and its chambers are of normal size and thickness The right myocardium measures 3 5 mm in thickness and the left, 10 to 15 mm The mitral valve has small fibrinous vegetations along its closing edge, suggesting a recent verrucous valvular endocarditic change. There is no scarring or calcification present Its circumference is 10.5 cm The remaining valves are normal and measure respectively: tricuspid, 12 5 cm, pulmonary, 8 5 cm, and aortic, 7 5 cm. The coronary arteries are fairly smooth and of good caliber

Histologic Findings. There are a few older small scars in the myocardium, especially in the papillary muscles Also, there is slight edema. In addition, firmly attached recent thrombi are seen between the trabeculae. Other sections show extensive older scarring in the myocardium together with numerous hemosiderin cells and with hypertrophy of the surrounding muscle fibers, representing small old infarct-like changes The epicardium is not involved, except for infiltration by cancer cells and edema There are no remarkable changes in the right ventricular myocardium, except for infiltration by fat tissue

The *heart valves* present distinct formations of small *verrucous protrusions* with considerable hyalinization and some mucoid degeneration of the thickened endocardium There is a firmly adherent fibrinoid exudate, partly organized and containing comparatively few leucocytes, this is distinctly liquefied in its basal attachment to the endocardium There are no specific rheumatic nodules.

CLINICAL PICTURE

The systemic picture includes fever, progressive anemia, pericarditis, white-centered petechiae, erythematous and purpuric rashes, embolic phenomena, enlarged liver and spleen, and other manifestations. It may well be *subacute* but occasionally there are alarming *acute episodes,* many of which involve the cardiovascular system. The physical signs from a cardiac standpoint are often difficult to evalu-

ate. The *systolic murmur* may be misinterpreted because of the presence of fever, anemia, and tachycardia. *Diastolic murmurs* may occur when verrucae involve the valve cusps or large lesions spread to the chordae tendineae. *Pericarditis,* usually dry and fibrinous (occasionally effusive) causes friction rubs which are frequently heard. Myocarditis, cardiomegaly, hypertension, cardiac failure, arrhythmia, and electrocardiographic evidence of conduction defects may occur in this order of frequency By the same token, the physical findings and clinical signs will depend upon the dominant complicating cardiac or cardiovascular involvement. The systolic murmur is nonspecific in character and distribution; the diastolic murmur, if present, could simulate the rumble of rheumatic mitral stenosis. The dry type of pericardial involvement may result in friction rubs, the effusive type may range from absence of signs to the evidences of *tamponade* Gallop rhythm and T-wave changes in the electrocardiogram have been accepted as evidences of myocarditis. Physical and radiographic evidence of cardiac enlargement and pulmonary congestion may be present. Shortness of breath, cough, rales, liver engorgement, and peripheral edema may occur. Disturbances of the heart rate and rhythm include sinus tachycardia, premature contractions, first and second degree AV block, and atrial fibrillation The disparity, so often present, between the clinical manifestations and the demonstrable pathologic changes at autopsy has been stressed by Griffith and Vural. When tachycardia occurs, it is out of proportion to the temperature rise. However, it should be kept in mind that lupus erythematosis can be superimposed on other cardiac processes including subacute bacterial endocarditis Dyspnea and other evidence of failure may be the result of direct myocardial damage or of involvement of the coronary vessels.

DIAGNOSIS

As has been suggested, the critical physician should always suspect this disease in atypical symptom complexes which often may include cardiac disturbances. The other processes involving the collagen tissues must always be considered because, as mentioned above, rheumatoid arthritis and acute rheumatic carditis share with lupus similar laboratory findings, short of an actual demonstration of the L E cell. A few rule-of-thumb distinctions may be mentioned at this point. White-centered petechiae do not tend to occur in rheumatic endocarditis Pericarditis seldom occurs in subacute bacterial endocarditis. Biopsy should rule out periarteritis in most instances Blood cultures will confirm acute or subacute bacterial endocarditis, and serum agglutinations give positive data in tularemia and in typhoid, paratyphoid, and undulant fevers. Uremic pericarditis may have to be ruled out.

TREATMENT

As concerns the cardiac factors in systemic lupus, the treatment differs little from that of heart failure or arrhythmia in other circumstances. Although cardiac failure is not considered a contraindication to hormone therapy, more careful sodium restriction is necessary when this course is taken. Digitalis and mercurials are used as in other types of congestive heart failure. Adequate rest is very important in the presence of cardiac involvement In regard to hormone treatment, it may be difficult to determine whether the failure is due to steroid therapy or to the progression of the disease *Prednisone,* in doses of 20 to 40 mg daily, seems the drug of choice because it has less sodium-retaining activity than other steroids. Supplementary use of oral or parenteral diuretics and potassium is helpful in maintaining water and electrolyte equilibrium As noted by Talbott and Ferrandis, there is no statistical evidence to date that steroid therapy affects the basic process underlying the disease, but there is overwhelming evidence that there is considerable symptomatic relief for variable periods of time. Therefore, congestive heart failure should not be considered as a reason for withholding this type of therapy.

4

The heart in glycogen disease

ISADORE SNAPPER

In 1927 van Creveld and Snapper studied a 7-year-old boy with a large liver, hypoglycemia, and acetonuria, but no splenomegaly. An exploratory laparotomy had been performed when the child was 8 months old because of progressive enlargement of the abdomen. At that time, the only finding was a large and soft liver which grossly gave the impression of being a fatty liver. Unfortunately, no biopsy had been performed.

During the admission in 1927, this child had marked hypoglycemia and acetonuria in the morning, together with a marked increase of the ketone bodies (both acetone and beta-hydroxybutyric acid) in the blood. During the blood sugar tolerance test, a biphasic blood sugar curve was obtained without the development of any clinical symptoms or signs of hypoglycemia. In the presence of acetonuria and acetonemia, the hypoglycemia could not be caused by either an insulinoma or a widespread hepatoma. Therefore the author considered the possibility that in this child the glycogen depots in the liver, probably also in the muscles, could not be transformed into glucose. This explanation was supported by the finding that injection of 0.5 mg of epinephrine, which in normal children causes hyperglycemia, was followed by a negligible rise in the blood sugar. In addition, after the injection, this child excreted a markedly increased quantity of acetone and beta-hydroxybutyric acid. In normal subjects, the metabolism of carbohydrates increases under the influence of an injection of epinephrine. Consequently, the respiratory quotient goes up and ultimately approaches unity. In the author's patient epinephrine had an opposite influence and the respiratory quotient decreased. The lowering of the respiratory quotient indicates an increase of the combustion of fats, another point which favored the opinion that glycogen was not available as a source of calories. This was later confirmed by the observation that, in similar cases, epinephrine does not cause a rise in the lactic-acid content of the blood, as it does in normal individuals.

One year later, von Gierke (1929) reported the autopsies of two children with large liver and large kidneys, in whom the enlargement of these organs was caused by an accumulation of glycogen. Since the glycogen, as determined by Schoenheimer, persisted in these organs for several days after the autopsy had been performed, von Gierke concluded that the glycogen must have been abnormal and must have been much less sensitive to enzymatic action than normal glycogen.

For many years van Creveld had pursued the study of the problems of glycogen disease. His follow-up of the first patient is highly interesting. Although, in 1927, this child gave the impression of suffering from an adiposogenital syndrome, he has developed into a normal man who, at the age of 30, was 1.83 m tall and weighed 89 kg. He had married and had a son. The liver was just palpable. The skeletal development was completely normal, although during his childhood delayed ossification had been present. The fasting blood sugar was completely normal and acetonuria was absent. Nevertheless—as was the case 23

years previously—after an injection of epinephrine, the blood sugar did *not* increase. However, the acetonuria was only slight. Van Creveld observed the same favorable course of events in a girl with glycogen disease of the liver. He first studied this patient when she was 5 years old and followed her until she reached the age of 24 years

Since Amsterdam is the place where glycogenosis of the liver was first recognized as a disease entity, it is no wonder that another form of glycogen disease, the so-called *cardiac or generalized type of glycogen storage disease,* was also first observed and described in the same city. In 1930 a 7-month-old girl was admitted to the hospital. She had a normal development and had been healthy until a few days before admission, when dyspnea had started. The child appeared sick, with a pale-cyanotic skin, sunken eyes, and severe dyspnea The heart appeared normal on percussion but the heart sounds were muffled Signs of pneumonia were present in the left lower pulmonary lobe. The child died 4 days later. The autopsy was performed by Pompe, who found a tremendously large and globular heart. The apex of the heart was formed by both ventricles. All valves were normal and no abnormal shunts were present The musculature of the left ventricle was hypertrophied and measured 29 mm without trabeculae The right ventricle measured 9 mm These figures should be compared with those of 7 to 10 mm for the left ventricle, and 2 to 5 mm for the right ventricle in an adult male. The coronary arteries were normal. There was bilateral bronchopneumonia, more pronounced at the left. Liver, spleen, adrenals, kidneys, and all other organs, were grossly normal

A diagnosis of "idiopathic hypertrophy of the heart" was made. However, two days later the heart muscle was examined in frozen sections, and the myocardium proved to consist of a network of round and oval meshes in which a nucleus, either in the middle of the cavity or at the lateral walls, was often found. It soon appeared that this remarkable picture, the so-called *lace-work appearance,* was due to a vacuolar change of the muscle fibers of the heart. In these changed fibrils, no fat was found Pompe felt that these abnormal fibrils were similar to the fibers of Purkinje He therefore examined the heart for the presence of glycogen and found that large amounts of glycogen were present in the heart muscle, and in all other organs.

Pompe insisted that this disease represents a glycogen infiltration of practically all organs. He also emphasized that, in the disease which now is called von Gierke's disease, the abnormal glycogen is present only in the enlarged liver and kidneys, not in the other organs, especially not in the heart. Pompe proposed for the disease he described the name of "cardiomegalia glycogenica," or, as he preferred, "glycogen depository disease." Pompe remarked that in the future, in every case of hypertrophy and dilatation of the heart without a clear-cut origin, the possibility of a glycogen heart must be considered. The diagnosis of generalized glycogenosis is much more difficult than the recognition of the hepatic form of glycogen disease. The metabolic changes which characterize the latter disease are absent in the cardiomegalic form. Only a muscle biopsy will reveal the presence of the generalized form of glycogen disease.

The clinical picture caused by the glycogen heart disease is nearly always the same as that described in Pompe's first patient, i e, attacks of dyspnea and cyanosis in a child with an enlarged heart. In a few cases heart murmurs have been heard. Malnutrition was nearly always present. At roentgenographic examination, the cardiac enlargement usually gave rise to a globular shaped shadow of the heart Electrocardiographic anomalies have been observed in several cases, but these changes can hardly be considered characteristic. The disease has been reported in siblings

All these children have succumbed below the age of 1 year. The gross pathologic and histologic changes in all cases were identical with the ones originally described by Pompe Retardation of the disappearance of the glycogen deposited in the different organs was nearly always present.

For the differential diagnosis, diffuse rhabdomyomatosis of the heart must be considered A few other cases of *focal* glycogen infiltration of the heart muscle have been described, in these the blood supply to the myocardium had suffered because of congenital anomalies of the blood vessels In cases of glycogen disease of the heart, biopsy of a skeletal muscle, as mentioned above, reveals an excessive deposition

of glycogen. In some cases, an increased glycogen content of the blood and even of the leucocytes has been found.

The disease is rare, so that by 1950 only 15 proved cases could be collected from the literature.

Neither the clinical picture, the roentgenogram of the heart, nor the electrocardiogram have contributed to a better understanding of the origin of the glycogen heart. In contrast, the study of the underlying biochemical anomalies of this disease has cleared up many problems. In 1928 it seemed possible that inhibition of the action of the diastatic enzymes could be responsible for the delayed degradation of glycogen to glucose. However, studies of the structure of the glycogen molecule and isolation of the enzymes which bring about the synthesis and the degradation of glycogen have proved that these enzymes are not responsible for glycogen disease.

The multibranched structure of the glycogen molecule is of great importance to a better understanding of the glycogen disease, because several different enzymes are required to build up this complicated molecule and also to change glycogen to glucose. Just as the favorable prognosis of the liver-kidney variety of the glycogen disease is completely different from the unfavorable outlook of the glycogen heart, so are the biochemical anomalies completely different. The structure of the glycogen found in the liver-kidney glycogen disease, is within the normal range. However, one specific enzyme, glucose-6-phosphatase, is absent in the liver and kidney of these patients. The normal enzymatic degradation of glycogen is prevented, and accumulation of abnormally stable glycogen in liver and kidney results.

In all cases of generalized glycogenosis, especially in the heart-storage disease, the glucose-6-phosphatase activity is normal. However, in some of these patients the so-called debranching and branching enzyme, i.e., amylo-1,6-glucosidase, is absent. This enzyme removes the branching chains which sprout out from the central core of the glycogen molecule and also synthesizes the branching chains to the central molecule. As a result, in the heart-storage disease, the outer branches of the glycogen molecule may be abnormally short and the degradation of this abnormal molecule is impaired. When this is the case, an abnormal, short-branched glycogen molecule accumulates in the tissues of the body, especially in the heart, and remains intact for many days after death.

It is certain that other biochemical varieties of this generalized glycogen disease exist. In certain cases, the glycogen molecules were normal in configuration and had outer branches of normal length. In some of these children, the amylo-1,6-glucosidase action was normal, but the enzyme activity was very low in at least one case.

It follows that many detailed problems still have to be worked out.

SUMMARY

The so-called *glycogen heart* is a modality of generalized glycogen storage disease. In the cardiac form of glycogenosis, glycogen is deposited in many tissues, but especially in the myocardium. All patients with glycogen heart have died below the age of 1 year, usually with attacks of dyspnea and cyanosis. The heart is always enlarged. This disease has no characteristic roentgenographic or electrocardiographic signs.

A favorable prognosis and characteristic changes in metabolism differentiate the liver-kidney form of glycogenosis from the so-called glycogen heart. It has now been shown that, in the liver-kidney form, the glycogen is normal but one specific enzyme, glucose-6-phosphatase, is absent. In certain cases of the cardiac form of the general storage disease, another enzyme, amylo-1,6-glucosidase, is absent and the structure of the glycogen molecule is abnormal. This difference is of basic importance for prognosis.

years previously—after an injection of epinephrine, the blood sugar did *not* increase. However, the acetonuria was only slight. Van Creveld observed the same favorable course of events in a girl with glycogen disease of the liver. He first studied this patient when she was 5 years old and followed her until she reached the age of 24 years.

Since Amsterdam is the place where glycogenosis of the liver was first recognized as a disease entity, it is no wonder that another form of glycogen disease, the so-called *cardiac or generalized type of glycogen storage disease*, was also first observed and described in the same city In 1930 a 7-month-old girl was admitted to the hospital. She had a normal development and had been healthy until a few days before admission, when dyspnea had started. The child appeared sick, with a pale-cyanotic skin, sunken eyes, and severe dyspnea. The heart appeared normal on percussion but the heart sounds were muffled. Signs of pneumonia were present in the left lower pulmonary lobe. The child died 4 days later. The autopsy was performed by Pompe, who found a tremendously large and globular heart. The apex of the heart was formed by both ventricles. All valves were normal and no abnormal shunts were present. The musculature of the left ventricle was hypertrophied and measured 29 mm without trabeculae. The right ventricle measured 9 mm These figures should be compared with those of 7 to 10 mm for the left ventricle, and 2 to 5 mm for the right ventricle in an adult male The coronary arteries were normal There was bilateral bronchopneumonia, more pronounced at the left. Liver, spleen, adrenals, kidneys, and all other organs, were grossly normal

A diagnosis of "idiopathic hypertrophy of the heart" was made However, two days later the heart muscle was examined in frozen sections, and the myocardium proved to consist of a network of round and oval meshes in which a nucleus, either in the middle of the cavity or at the lateral walls, was often found It soon appeared that this remarkable picture, the so-called *lace-work appearance*, was due to a vacuolar change of the muscle fibers of the heart. In these changed fibrils, no fat was found. Pompe felt that these abnormal fibrils were similar to the fibers of Purkinje He therefore examined the heart for the presence of glycogen and found that large amounts of glycogen were present in the heart muscle, and in all other organs.

Pompe insisted that this disease represents a glycogen infiltration of practically all organs. He also emphasized that, in the disease which now is called von Gierke's disease, the abnormal glycogen is present only in the enlarged liver and kidneys, not in the other organs, especially not in the heart. Pompe proposed for the disease he described the name of "cardiomegalia glycogenica," or, as he preferred, "glycogen depository disease." Pompe remarked that in the future, in every case of hypertrophy and dilatation of the heart without a clear-cut origin, the possibility of a glycogen heart must be considered. The diagnosis of generalized glycogenosis is much more difficult than the recognition of the hepatic form of glycogen disease. The metabolic changes which characterize the latter disease are absent in the cardiomegalic form Only a muscle biopsy will reveal the presence of the generalized form of glycogen disease.

The clinical picture caused by the glycogen heart disease is nearly always the same as that described in Pompe's first patient, i e., attacks of dyspnea and cyanosis in a child with an enlarged heart. In a few cases heart murmurs have been heard. Malnutrition was nearly always present. At roentgenographic examination, the cardiac enlargement usually gave rise to a globular shaped shadow of the heart Electrocardiographic anomalies have been observed in several cases, but these changes can hardly be considered characteristic. The disease has been reported in siblings

All these children have succumbed below the age of 1 year. The gross pathologic and histologic changes in all cases were identical with the ones originally described by Pompe Retardation of the disappearance of the glycogen deposited in the different organs was nearly always present.

For the differential diagnosis, diffuse rhabdomyomatosis of the heart must be considered A few other cases of *focal* glycogen infiltration of the heart muscle have been described, in these the blood supply to the myocardium had suffered because of congenital anomalies of the blood vessels. In cases of glycogen disease of the heart, biopsy of a skeletal muscle, as mentioned above, reveals an excessive deposition

paramyloidosis, of the tongue causes macroglossia, of the heart, myocardial failure; of the larynx, difficulties in speech, of the esophagus, difficulties in swallowing, of the gastrointestinal tract, gastric and intestinal hemorrhages, of the subcutaneous tissue, waxy, often hard, subcutaneous masses and also, sometimes, alopecia, of the lymph nodes, lymphadenopathy; of the pulmonary tissue, dyspnea and remarkable roentgenographic pictures Amyloid deposition in the bone marrow is usually found only at a bone-marrow puncture.

As the location and the tinctorial characteristics of this form of amyloidosis differ from that which develops after suppuration, it is advisable to designate it paramyloidosis The term primary amyloidosis, often used, is hardly appropriate since this form only rarely occurs in the absence of a clear-cut origin.

There is one localization which is characteristic of paramyloidosis in patients with multiple *myeloma* In the latter disease, paramyloid is often localized on the synovial capsules of the articulations, whereas this is rare in patients who do not suffer from multiple myeloma

In paramyloidosis, liver, spleen, kidneys, and adrenals may also be involved because amyloidosis of the arterial walls occurs both in the secondary form and in paramyloidosis. However, the tremendous amounts of amyloid found in secondary amyloidosis are never pres-ent [illegible]

[illegible] dye after injection is rapidly taken up by the amyloid of the different organs and disappears from the blood serum The more amyloid present in the body, the more dye is removed from the blood stream Thus the Congo-red test is only positive when the deposition of amyloid is very extensive, as in patients in whom nearly the entire liver is replaced by amyloid If the infiltration of the liver is limited, then the Congo-red test cannot be positive, even if kidneys, spleen, and adrenals are involved The amount of amyloid deposited in the latter organs can never be sufficient to absorb so much Congo red that all the dye disappears from the serum It follows that the Congo-red test is only positive in cases of so-called secondary amyloidosis with extensive involvement of the liver, it is often negative in secondary amyloidosis and is never positive in paramyloidosis.

2. Amyloidosis of the kidneys may give rise to severe *proteinuria, hypoproteinemia, edema,* and ultimately *uremia.* This is only observed in cases of so-called secondary amyloidosis, where the kidney in its entirety is involved. If a patient with paramyloidosis develops uremia, then this is never due to the scanty paramyloid infiltration of the blood vessels of the kidney. A patient with paramyloidosis and uremia always suffers from multiple myeloma, and in such cases the uremia is due to the blockage of the tubules by Bence Jones protein, not to the infiltration of the arteriolar walls with amyloid. Significant quantities of Bence Jones protein will always be found in the urine of patients with multiple myeloma and uremia.

3. *Biopsy of the gums* has been advocated for the diagnosis of amyloidosis because amyloid may be present in the arteriolar walls of the submucous layer of the gingiva. This biopsy is only rarely positive in secondary amyloidosis but is certainly important for the diagnosis of paramyloidosis.

4. *Puncture of liver and spleen,* which is often positive in secondary amyloidosis, is of little help in the laboratory diagnosis of paramyloidosis

5. There are several cases on record in which the autopsy of a patient who had suffered from heart failure of unknown origin revealed paramyloidosis of the heart muscle. Only then was the possibility of multiple myeloma considered Examination of the bone marrow in such cases usually proved the existence of generalized myelomatosis.

Since the rarity of tuberculosis, osteomyelitis, syphilis, and leprosy has led to a marked decrease of the cases of secondary amyloidosis, the interest in paramyloidosis has markedly increased

As far as the heart is concerned, cardiac failure does occur, though rarely, in patients with secondary amyloidosis in whom only the arterial system of the heart is involved. Cardiac failure has been observed much more frequently in cases of paramyloidosis, in which the musculature is the prevalent site for it [illegible]

[illegible] myeloma, is usually enlarged

Amyloid Heart Disease

The Heart in Amyloidosis Complicating Multiple Myeloma

ELWYN EVANS

MULTIPLE MYELOMA AND AMYLOID DISEASE

Although *multiple myeloma* is a disease which occurs in all age groups, except during the first decade, it is especially frequent in persons over 40. Therefore, in patients with multiple myeloma and heart failure, the possibility of coronary heart disease must always be considered. Another cause of heart failure in multiple myeloma is associated with the frequent occurrence in this disease of abnormal metabolism of proteins. In this connection Bence Jones proteinuria, hyperglobulinemia, and, especially, amyloidosis must be mentioned. Deposition of amyloid is found in 10 per cent of the patients with multiple myeloma. This form of amyloid degeneration, so-called *paramyloidosis,* frequently involves the myocardium and may lead to intractable myocardial failure

The semantics of this condition are thoroughly confused because the terms "primary" and "secondary" amyloidosis have different meanings for different authors Until 1940, widespread deposition of amyloid, commonly designated as secondary amyloidosis, was often found in the wake of long-standing suppuration and fistulization, especially in cases of tuberculosis, osteomyelitis, syphilis, leprosy, and other chronic diseases With the advent of appropriate antibiotics this form has become relatively rare. Amyloidosis was observed less frequently in patients with chronic rheumatoid arthritis, Hodgkin's disease, and malignant tumors, especially hypernephroma. Occasionally a patient who had not suffered from any of these ailments surprised his physicians when, at autopsy, widespread amyloidosis was discovered. In all these conditions the amyloid deposition was mainly localized in the liver, spleen, kidneys, adrenals, and in the walls of larger and smaller arteries Because the localization of amyloid was always identical, this disorder was commonly designated as *secondary amyloidosis,* even in cases where no clear-cut cause for the degeneration could be found.

Due to deposition in the arterial walls, even in this form, the characteristic substance can be deposited in any organ, including the heart. Arterial amyloidosis usually is not extensive and does not interfere with the function of the involved organ. Exceptions to this rule, however, do occur and severe heart failure has been reported in cases where the so-called secondary amyloidosis had led to widespread involvement of the myocardium.

So-called *primary amyloidosis* or *paramyloidosis* may develop in patients with multiple myeloma. It is mainly localized in striated and smooth musculature, i.e., in the tongue, heart, arterial and arteriolar walls, larynx, esophagus, stomach, and intestines. It also often involves the subcutaneous tissue, lymph nodes, bone marrow, and other parts of the body, e g , the interalveolar septa of the lungs. Primary, or

SUMMARY

In every patient with multiple myeloma and heart failure, the diagnosis of amyloid disease of the heart muscle must be suspected. A rapidly rising pressure and a decreased ventricular systole favor the presence of paramyloidosis The diagnosis is certain if paramyloid is present in subcutaneous tissue or in the subgingival tissue obtained by biopsy.

AMYLOID HEART DISEASE

Cardiac amyloidosis, a rare but distinct type of organic disease in which amyloid deposits occur only or predominantly in the heart, has been receiving increasing attention in recent years Clinical findings are thought to be related to variable deposits of amyloid in the myocardium, pericardium, valves, and the smaller blood vessels.

Although Heubschmann (1907) reported eight cases with amyloid in the heart, and many have been reported since, only four cases of amyloidosis primarily involving the heart were reported by 1930 (Wild; Steinhaus; Beneke and Bonning; Larsen). Cardiac amyloidosis in all probability is a part of systemic amyloid disease and cardiac amyloid involvement is common in primary systemic amyloidosis, as well as in amyloid disease complicating multiple myeloma, and is not rare in secondary amyloidosis, therefore, amyloid disease per se needs to be discussed.

Despite the fact that accurate classification of amyloidosis is impossible because of overlapping of the different types, classification does serve a useful purpose

Lubarsch (1929) distinguished the primary form from the secondary form by (1) the absence of specific causative factors such as tuberculosis, chronic suppurative disease, and rheumatoid arthritis, (2) minimal or no deposition of amyloid in the liver, spleen, kidneys, and adrenal glands, sites of major deposition in the secondary type, (3) maximal deposition in the heart, lungs, skin, digestive tract, and striated muscle, sites not usually involved in the secondary type, (4) tumor formation, and (5) atypical reactions to specific amyloid stains

Reimann et al (1935) proposed the classification most widely used Based on clinicopathological features, they divided amyloidosis into (1) primary, (2) secondary, (3) tumor forming, and (4) that associated with multiple myeloma

ETIOLOGY

It is probable that when the basic cause of amyloidosis is known, all cases will be classified as secondary.

There is no known inciting cause in the primary systemic form which tends to occur in mid-life or later and in an older age group than the secondary form. In 46 cases of primary amyloidosis reviewed by Eisen, ages ranged from 34 to 90 years with an average of 46 years Heredity is a factor in some cases at least. Maxwell and Kimble (1936) were the first to report the familial pattern. Block et al. made extensive genetic studies on 60 members of a family in which there was familial primary systemic amyloidosis; 29 of them had evidence of the disease, and the investigators found it to have a dominant hereditary characteristic.

Age and sex are important factors when amyloid deposits are limited to the heart; these cases usually occur in men over 70 years of age The average age in 29 cases was 82 years (Josselson et al). Although the disorder with amyloid localized in the heart is usually considered a variation of the primary type, the presence of carcinoma in 12 and of multiple myeloma in 1 of the 29 cases is striking Secondary amyloidosis is associated with such inciting diseases as tuberculosis, chronic suppuration, rheumatoid arthritis, carcinoma, Hodgkin's disease and other less commonly associated diseases Amyloidosis associated with multiple myeloma is really secondary to this disease, but is considered separately because its body distribution and staining qualities are similar to those of the primary form.

PATHOGENESIS

Pathogenesis of amyloidosis is unknown There have been numerous theories, but the most favored one is that amyloidosis is related to hyperglobulinemia (Magnus-Levy, 1952, Reimann et al). This relationship has been suggested because of the frequent coexistence of amyloidosis and hyperglobulinemia in cases of multiple myeloma; in horses used for antiserum production, in various animals given repeated injections of bacterial vaccines, and

and its weight is frequently increased to 500 to 600 Gm. Occasionally, at gross examination, a remarkable rigidity and diminished elasticity, together with waxiness of the myocardium, have been found. Both atria and ventricles are often equally involved. Sometimes the cross sections of the myocardium reveal the presence of translucent grayish streaks or patches of amyloid tissue which occasionally completely replace the heart-muscle tissue. Although total obliteration of the arterial lumen by paramyloid rarely occurs, amyloid cushions may project into the lumens of the arteries, especially in the smallest vessels. Due to frequent involvement of the muscular layers of the smaller arteries, ischemic changes of the myocardium with focal areas of necrosis are frequently widespread, while grossly visible necrosis of the heart muscle is rare.

The amyloid deposits may continue from the myocardium into the epicardium and even into the endocardium. The latter are often present in the ventricular aspects of the AV valves near the free margin of the cusps. There may also be uniform thickening of one or more cusps due to subendothelial infiltration of the valve. The mitral and tricuspid valves have been found to be more frequently involved than the aortic or pulmonary valves. Ultimately, the dynamics of such an amyloid valve may be similar to the ones seen in rheumatic heart disease

In the pericardium there may be flattened or round nodules of amyloid deposits

Clinically, amyloidosis of the heart presents an *intractable and progressive heart failure* with or without heart block or other disturbances of the cardiac rhythm Since clear-cut closure of coronary arteries by amyloid is rare, the typical electrocardiogram of myocardial infarction is hardly ever found. Electrocardiography reveals *low voltage* in all leads with *depression of S-T segment, inversion of the T waves, delayed AV conduction,* and irregular rhythm.

The diagnosis of amyloidosis of the heart muscle must be considered in all cases of heart failure of unknown origin which do not react to appropriate therapy. The diagnosis is usually difficult. In this connection, it may be mentioned that the differentiation between paramyloid of the myocardium and rheumatic valvular disease may be impossible, because amyloid of the mitral valve may lead to all the auscultatory signs of a typical mitral valvulitis.

Simultaneous occurrence of heart failure and *polyneuritis* of unknown origin is a strong point in favor of extensive paramyloidosis of the heart muscle.

In every case where the diagnosis of paramyloid disease of the heart muscle is suspected, a *sternal marrow puncture* is mandatory. The greater part of the cases of paramyloid disease of the heart muscle which cause failure are due to multiple myeloma. On the other hand, when, in a patient with heart failure, the bone-marrow puncture proves the presence of multiple myeloma, amyloidosis of the myocardium must be seriously considered.

Gunnar et al. (1956) proved that amyloid infiltration of the heart causes an inability to augment the diastolic volume and underlined the clinical similarities between *amyloidosis* of the heart and constrictive pericarditis. In both conditions, the following signs are encountered:

1. Ascites occurs early, is persistent and, in the later stages, is accompanied by peripheral edema

2. Venous pressure is high, pulse pressure is low.

3 A paradoxical pulse may be present

4. The electrocardiographic changes are nonspecific.

5. There is little or no response to conventional treatment of cardiac failure.

Thus, it can be understood that, in certain cases of myocardial amyloidosis, surgical procedures have been erroneously performed

As emphasized by Gunnar et al , catheterization reveals in both diseases that the diastolic filling of the ventricles is markedly impaired. This is due in constrictive pericarditis to the incarceration of the ventricle by scar tissue, this leads to the loss of the elasticity of the epicardium and the superficial myocardial muscle layers. In amyloidosis of the heart, the abnormal protein, amassed between the muscle fibers, interferes with the diastolic expansion of the ventricles. Catheterization of the right ventricle registers an early diastolic dip, then a sudden rise, and high end-diastolic pressure. The right atrial pressure is, of course, abnormally high.

Cardiac output is diminished and systolic pressure is much lower than expected in the presence of a high diastolic pre[illegible]re.

25 each, extremity pain in 19, enlarged lymph nodes in 18, abdominal pain in 10, hematuria in 5, hematemesis in 4, fever in 3, and purpura in 1.

Myocardial failure was sufficiently severe to be considered the cause of death in 25 of 46 cases (Dahlin, 1949a).

In the cases in which amyloid deposition is confined to the heart, the signs and symptoms are those of congestive failure in patients about 70 years of age or older, usually males In 15 of these patients, atrial fibrillation was found on seven occasions (Josselson and Pruitt)

Occasionally, *chronic constrictive pericarditis is simulated* (Findley and Adams; Gunnar et al). In both conditions, there is a loss of distensibility and resistance to contraction, and clinically there may be narrow pulse pressures, feeble cardiac pulsations, high venous pressures, evidence of myocardial failure unresponsive to usual forms of therapy, and nonspecific electrocardiographic changes.

When organs other than the heart are involved, signs and symptoms related to these structures naturally appear. In macroglossia, the tongue is usually hard and nontender, and is often associated with dysphagia and dysarthria. When the trachea, mediastinum, or the vessels of the lungs are involved, dyspnea may be associated with a picture of chronic cor pulmonale

Contrary to the general belief, involvement of the liver and spleen is not uncommon in the primary systemic form When it is sufficiently infiltrated, it may be palpably enlarged, hard, and not tender unless the enlargement is partly due to congestive heart failure. Liver function may or may not be impaired, but clinical evidence of serious impairment of liver function is not common Ascites was present in 29 per cent of 71 cases reported by Higgins and Higgins Jaundice is uncommon, but was present in 7 of 50 cases reviewed by Mathews When the spleen is involved, it may be palpably enlarged, but usually not greatly. The gastrointestinal tract was involved in 33 of 54 patients, five of whom had serious hemorrhages (Dahlin, 1949) The gastrointestinal symptoms and signs have been diarrhea, constipation, abdominal pain, nausea, vomiting, distention, intestinal hemorrhage ...

About one-third of the patients with systemic amyloidosis tend to develop the nephrotic syndrome which varies in severity from albuminuria with edema to the full-blown picture of nephrosis (Pruitt et al.). Occasionally, there is sufficient amyloid involvement of the glomeruli to cause azotemia.

Lindsay found skin lesions described as opalescent and papular, or opalescent, firm, nodular, sclerodermic, and papular, with plaquelike scleroderma, weeping eczema, and pink striae beneath the nails of the fingers and toes. Mathews mentioned purpura or petechiae in 9 of the 50 cases he reviewed Occasionally, muscular, joint, or tendon involvement is associated with some joint distress or ... ment m... like, bu... say).

Secondary Amyloidosis. Signs and symptoms of organ involvement in the secondary form occurs most often in cases with renal infiltration, especially when the nephrotic syndrome is present. Dahlin (1949) observed albumin in 26 of 27 cases, but renal failure was severe in only three Muscle involvement and macroglossia are absent. Although the heart is involved in only about 10 per cent of cases of the secondary type, signs and symptoms are similar to those of the primary type with enlargement and progressive, unresponsive congestive failure. Hepatomegaly with an enlarged, hard, and nontender liver is the main evidence of liver involvement, occurring in two-thirds of 102 cases, but disturbance of liver function is only evident occasionally. Jaundice has been noted only three times in the literature. Splenomegaly, usually slight to moderate, may be noted. In spite of the fact that most authors emphasize frequent involvement of the adrenal glands pathologically, especially in the secondary type, impairment of adrenal function is rarely mentioned in either type. Although clinical evidence of Addison's disease is not frequent in amyloidosis, amyloid involvement of the adrenals was the third most common cause of Addison's disease in O'Donnell's series In 29 cases of moderately advanced adrenal amyloidosis, evidence of hypoadrenocortical function was present in only three

LABORATORY STUDIES

CONGO-RED TEST The Congo-red test is the only laboratory procedure of real diagnostic value other than biopsy of pathologic material ... this test ... of sufficient amyloid de-

in rabbits fed or injected with sodium caseinate.

Even the site of formation of amyloid is disputed. The two main views are: (1) Amyloid is deposited primarily in or on the cell membrane (Peters, 1943). (2) It is deposited beneath the capillary endothelium, whence it spreads (Larsen). Magnus-Levy (1952) thinks that amyloid is formed in the plasma cell and that Herbut and Erf and Bayrd and Bennett proved this theory when they found amyloid within the myeloma plasma cell, since this cell is not phagocytic.

PATHOLOGICAL CHANGES

Reviewing 70 cases of primary amyloidosis, Dahlin (1949a) noted a marked tendency to involve the heart, lungs, muscles (smooth and striated), skin, and other structures of mesodermal origin not often involved, at least to a serious degree, in secondary amyloidosis. Eisen, reviewing 46 primary cases with autopsy studies found the myocardium to be involved in 85 per cent, endocardium, in 61 per cent, pericardium, in 48 per cent, valves, in 37 per cent, stomach, in 57 per cent, small intestine, in 52 per cent, colon and tongue, each in 48 per cent, skin and spleen, each in 27 per cent; kidneys, in 26 per cent, and liver and lymph nodes, each in 17 per cent.

The bulk of cardiac amyloid is myocardial in distribution, the myocardium being firm and resistant to cutting. All chambers may be involved, and may be hypertrophied, thickened, stiff, and leathery. When amyloid is grossly visible in the heart, it appears patchy or diffuse, translucent, waxy, and grey, pinkish, or yellowish. Macroscopically, it becomes brownish with the application of iodine and turns darker with the addition of dilute sulfuric acid.

Microscopically, amyloid is diffusely deposited throughout the interstitial tissue, and muscle fibers become atrophic, fragmented, vacuolated, or necrotic. Amyloid is found in the veins, capillaries, arterioles, and sometimes in any or all layers of the larger coronary arteries (Mathews).

In elderly individuals, 70 years of age or more, deposits may be confined to the heart, these are usually small and confined in distribution, but occasionally are large. Josselson et al. (1952), studying 29 cases of amyloid disease localized in the heart, found atrial endocardial deposits to be grossly recognizable in 22 of them. The atrial endocardial deposits appeared as tiny, translucent, grey, or pink elevations either in localized collections or deposited diffusely. While the atrial endocardium showed quite striking changes, the ventricular endocardium usually showed little or no change. In 3 of 13 cases reported as amyloidosis localized in the heart, small amounts of amyloid also were found in the lung or prostate gland (Josselson et al, 1950).

In the primary form, the amyloid, to variable degrees, stains red with Congo red, periodic acid, and leucofuchsin; metachromatically reddish-violet with methyl or crystal violet and methyl green; brownish with iodine; and yellow or pale pink with van Gieson's stain

The secondary type predominantly involves the liver, spleen, kidneys, and adrenal glands Occasionally the heart is involved, rarely extensively. Dahlin (1949b) found the spleen to be involved in 100 per cent; kidneys, in 93 per cent; liver, in 87 per cent; lymph nodes, in 68 per cent; gastrointestinal tract, in 55 per cent; heart, in 10 per cent; and striated muscle 0 per cent. The liver was *not often* infiltrated extensively.

The amyloid found in secondary amyloidosis stains consistently and typically with the various amyloid stains

CLINICAL DESCRIPTION

Signs and symptoms are extremely variable in number and severity because of variations in the number of organs involved and the extent of the involvement.

Primary Amyloidosis. Despite the variability of signs and symptoms in the primary form, a fairly definite clinical pattern is not uncommonly revealed with persistent, unresponsive myocardial failure of unknown origin associated with macroglossia in 42 per cent, asthenia in 42 per cent, and weight loss in 31 per cent. This pattern is not likely to be seen in any other condition and differentiates the primary form clinically from the secondary form In a series of 71 cases of primary systemic amyloidosis reviewed by Higgins and Higgins, *congestive failure* was present in 40 patients (56 per cent), *dyspnea and edema* were present in 39 per cent of these patients, *ascites* in 19 per cent, and *hydrothorax* in 18 per cent Macroglossia was present in 25 patients, 18 of them had dysarthria and 15, dysphagia General muscular weakness was present in 36 patients, skin and buccal membrane deposits in

wave abnormalities in twelve. Serial changes were noted in four cases in which more than one electrocardiogram was taken.

Josselson et al. (1953) studied the electrocardiograms of 15 patients found to have amyloid in their hearts at autopsy. Four were primary systemic, ten amyloidosis localized in the heart, and one cardiac amyloidosis associated with multiple myeloma. The tracings were abnormal in twelve cases. The most common abnormality was low voltage of the QRS complexes in the standard limb leads. It was interesting that *atrial fibrillation* was present in seven patients. This was thought to be abnormally high because electrocardiograms had been taken on the basis of suspected cardiac disease, and atrial fibrillation is an indication for obtaining an electrocardiogram. There were two cases with *complete* AV block, but there were no prolonged P-R intervals otherwise, and none of the electrocardiograms justified the diagnosis of myocardial infarction. *Low voltage* of the QRS complexes in leads V_1, V_2, and V_3, with normal complexes between and in the transitional zone was commented upon. Mild atherosclerosis was common, but not sufficient to be clinically significant.

Although the electrocardiographic findings are not specific for cardiac amyloidosis, low voltage of the QRS complexes in the standard limb leads and low, isoelectric or diphasic T waves with or without impairment of AV conduction or atrial fibrillation *are not especially* common in other diseases, and when considered with the clinical pattern and other laboratory tests, the electrocardiogram may be suggestive.

URINALYSIS. The kidneys were involved in 93 per cent of the secondary cases, and about one-third of the patients with the primary form developed the nephrotic syndrome (Dahlin, 1950). Renal involvement is *usually manifested* (1) by albuminuria of various degrees, *occasionally* massive, (2) occasionally by fixed specific gravity and (3) by findings associated with azotemia.

BLOOD COUNT. The blood count *frequently* revealed a hypochromic normocytic anemia of variable degree, but nothing otherwise significant. The sedimentation rate *is frequently increased* in the primary type, often *slightly to moderately*. In the secondary form, the blood *count often* shows secondary anemia and some leucocytosis. The sedimentation rate *is* often elevated.

LIVER FUNCTION STUDIES. Although the liver is almost universally involved in the secondary form and in about 30 to 40 per cent of the patients with the primary form, it often is not infiltrated sufficiently to show liver dysfunction. Severe liver disturbance is only occasionally noted, although it is not uncommon to observe some Bromsulphalein retention, together with elevation of alkaline phosphatase and serum cholesterol, hypoalbuminemia, and normal serum bilirubin. Abnormal cephalin flocculation and thymol turbidity tests are rare. The picture often simulates biliary obstruction without elevation of serum bilirubin.

CATHETERIZATION STUDIES. Catheterization studies in cases simulating chronic constrictive pericarditis yielded results indistinguishable from those of constrictive *pericarditis* (Gunnar et al; see also Chap. 12, Cardiac Catheterization in Subendocardial Fibroelastosis and Constrictive Diseases).

SERUM ELECTROPHORETIC STUDIES. Block *et al.* studied serum electrophoretic *findings in* 60 members *of a family* in which there was familial primary systemic amyloidosis. Twenty-nine patients showed an atypical protein peak in the $alpha_2$ and beta globulins, 14 of them showed poor resolution *in the* $alpha_2$ *globulin region*. All patients with clinical manifestations of the disease had *atypical* electrophoretic patterns, *but* 18 of the patients with abnormal electrophoretic patterns had no clinical manifestations.

LIPOPROTEIN STUDIES. Rukavina et al. made serum lipoprotein studies on 33 members of the family mentioned above, and found elevations of *the* $-S$ *fractions in* 27 of them. There appeared *to be a correlation between* the lipotrophic changes *and clinical* manifestations.

DIAGNOSIS

Diagnosis of amyloidosis limited to the heart is practically impossible, but may be suspected when intractable congestive heart failure of unknown origin appears in elderly persons about the age of 70 years or beyond, especially men.

Although electrocardiographic abnormalities are common at this age and electrocardiographic changes in cardiac amyloidosis are nonspecific, low voltage of the QRS complexes in the standard limb leads associated with T-wave abnormalities with or without atrial fibrillation or impaired AV conduction, should be suggestive, especially when associated with the clinical picture described above.

posits in the body and the frequent lack of affinity for the dye by the amyloid that is present. It is positive in less than half of the primary cases and is usually equivocal. Another objection to the use of intravenous Congo red is that it is not entirely safe. It should be used with caution in elderly individuals and in patients who have previously received the dye. Selikoff and Bernstein reported six serious systemic reactions, with two fatalities, in 100 consecutive cases in which the intravenous dye was used. All patients with severe reactions had received the dye previously without reaction It also should be used with caution when the skin is involved, and perhaps should not be used at all when skin involvement is extensive or in exposed surfaces because of the possibility of stubborn, fiery-red staining of the tissues.

Bennhold considered 60 per cent removal of the dye from the serum between 4-min and 60-min samples presumptive evidence of systemic amyloidosis. Because false-positive results occasionally appear, several investigators have modified Bennhold's technique, but none of the modifications have eliminated the basic criticism that variable amounts of the dye are absorbed by nonamyloid tissues, thereby making impossible the diagnosis of amyloid in the tissue in minimal or early cases To eliminate false-positive results, the criterion of 90 to 100 per cent removal of the dye in the 1-hr sample has been suggested Unger et al removed specimens at 2- or 4-min and 30-min intervals, and considered removal of 35 per cent of the dye between the 2- or 4-min and 30-min specimens as presumptive evidence of amyloidosis.

The intravenous Congo-red test is of more value in the secondary type of amyloidosis because of more frequent and often more extensive liver involvement. The test also is likely to be more positive in secondary amyloidosis because of the much greater affinity of the amyloid tissue for the dye in this type of the disorder.

Local injections of Congo red may be used when mucous membrane or skin lesions are present. It is a useful test, but tissues may not take the dye up readily in primary cases Here too, it must be remembered that skin discoloration may persist

TISSUE BIOPSY. Biopsy of the involved tissue is the only certain diagnostic measure It is also of special value in those cases with skin involvement because it avoids the danger of persistent staining. Biopsy occasionally may be falsely negative because the particular section taken does not happen to contain amyloid material and, in the primary systemic type, because of lack of affinity of the amyloid tissue for the various amyloid stains Biopsy of the tongue, mucous membranes, striated muscles, skin, tendons, liver, and even the stomach have yielded positive and diagnostic results in primary systemic amyloidosis. Biopsy of the liver and spleen in the secondary type have occasionally been diagnostic. Needle biopsies of the liver were positive in seven cases thought to have primary systemic amyloidosis (Pruitt et al, 1953). Unfortunately, differences between the primary and secondary forms are not always clear-cut, and Pruitt et al mentioned this. Because of one reported case of fatal hemorrhage from the liver following liver biopsy, Pruitt et al advise that, if congestive failure is evident, appropriate treatment should be carried out for several days before the liver biopsy in order to reduce the venous pressure as much as possible.

Selikoff and Robitzek performed gingival biopsies on 47 patients with secondary amyloidosis without gross evidence of gingival involvement. Biopsies were positive in 14 of 18 patients in whom the diagnosis of amyloidosis could be made with reasonable certainty. These authors recommended biopsy of gingival tissues because of their accessibility, the simplicity of the technique, the resistance of the tissues to infection, and the freedom from danger of severe hemorrhage.

Because cardiac amyloidosis may occasionally simulate chronic constrictive pericarditis (Maxwell and Kimble, Gunnar et al.) and pericardiectomy might be contemplated, Josselson et al. (1952) suggested *myocardial biopsies* in these cases before pericardiectomy is done. Sections of the left atrial appendage were studied in 11 of their 29 cases of amyloidosis localized in the heart, and amyloid was found in 7 of the 11 cases.

ELECTROCARDIOGRAM The electrocardiogram is usually abnormal when amyloid deposits are present in the heart, but changes are non-specific, although the particular findings may be suggestive when considered with the rest of the picture. Wessler and Freedburg presented two cases, and analyzed the electrocardiograms in nineteen published cases in which the electrocardiograms were recorded. Their two cases showed definite Q waves in the precordial leads suggestive of anterior myocardial infarction. An autopsy on one of these patients showed amyloid deposits but no infarct, fibrosis, or narrowing of the coronary vessels. No uniform pattern was elicited, but all electrocardiograms were abnormal There was prolongation of the P-R interval in six patients, low voltage of the QRS complexes in the standard limb leads in twelve, deep Q waves in the precordial leads in two, and P-

wave abnormalities in twelve. Serial changes were noted in four cases in which more than one electrocardiogram was taken.

Josselson et al. (1953) studied the electrocardiograms of 15 patients found to have amyloid in their hearts at autopsy: four were primary systemic; ten amyloidosis localized in the heart, and one cardiac amyloidosis associated with multiple myeloma. The tracings were abnormal in twelve cases. The most common abnormality was low voltage of the QRS complexes in the standard limb leads. It was interesting that *atrial fibrillation* was present in seven patients. This was thought to be abnormally high because electrocardiograms had been taken on the basis of suspected cardiac disease, and atrial fibrillation is an indication for obtaining an electrocardiogram. There were two cases with *complete AV block*, but there were no prolonged P-R intervals otherwise, and none of the electrocardiograms justified the diagnosis of myocardial infarction. *Low voltage* of the QRS complexes in leads V_1, V_5, and V_6, with normal complexes between and in the transitional zone was commented upon. Mild atherosclerosis was common, but not sufficient to be clinically significant.

Although the electrocardiographic findings are not specific for cardiac amyloidosis, low voltage of the QRS complexes in the standard limb leads and low, isoelectric or diphasic T waves with or without impairment of AV conduction or atrial fibrillation are not especially common in other diseases, and when considered with the clinical pattern and other laboratory tests, the electrocardiogram may be suggestive.

URINALYSIS. The kidneys were involved in 93 per cent of the secondary cases, and about one-third of the patients with the primary form developed the nephrotic syndrome (Dahlin, 1950). Renal involvement is usually manifested (1) by albuminuria of various degrees, occasionally massive, (2) occasionally by fixed specific gravity and (3) by findings associated with azotemia.

BLOOD COUNT. The blood count frequently revealed a hypochromic normocytic anemia of variable degree, but nothing otherwise significant. The sedimentation rate is frequently increased in the primary type, often slightly to moderately. In the secondary form, the blood count often shows secondary anemia and some leucocytosis. The sedimentation rate is often elevated.

LIVER FUNCTION STUDIES. Although the liver is almost universally involved in the secondary form and in about 30 to 40 per cent of the patients with the primary form, it often is not infiltrated sufficiently to show liver dysfunction. Severe liver disturbance is only occasionally noted, although it is not uncommon to observe some Bromsulphalein retention, together with elevation of alkaline phosphatase and serum cholesterol, hypoalbuminemia, and normal serum bilirubin. Abnormal cephalin flocculation and thymol turbidity tests are rare. The picture often simulates biliary obstruction without elevation of serum bilirubin.

CATHETERIZATION STUDIES. Catheterization studies in cases simulating chronic constrictive pericarditis yielded results indistinguishable from those of constrictive pericarditis (Gunnar et al.; see also Chap. 12, Cardiac Catheterization in Subendocardial Fibroelastosis and Constrictive Diseases).

SERUM ELECTROPHORETIC STUDIES. Block et al. studied serum electrophoretic findings in 66 members of a family in which there was familial primary systemic amyloidosis. Twenty-nine patients showed an atypical protein peak in the $alpha_2$ and beta globulins, 14 of them showed poor resolution in the $alpha_2$ globulin region. All patients with clinical manifestations of the disease had atypical electrophoretic patterns, but 16 of the patients with abnormal electrophoretic patterns had no clinical manifestations.

LIPOPROTEIN STUDIES. Rukavina et al. made serum lipoprotein studies on 33 members of the family mentioned above, and found elevations of the $-S$ fractions in 27 of them. There appeared to be a correlation between the lipotrophic changes and clinical manifestations.

DIAGNOSIS

Diagnosis of amyloidosis limited to the heart is practically impossible, but may be suspected when intractable congestive heart failure of unknown origin appears in elderly persons about the age of 70 years or beyond, especially men.

Although electrocardiographic abnormalities are common at this age and electrocardiographic changes in cardiac amyloidosis are nonspecific, low voltage of the QRS complexes in the standard limb leads associated with T-wave abnormalities with or without atrial fibrillation or impaired AV conduction, should be suggestive, especially when associated with the clinical picture described above.

posits in the body and the frequent lack of affinity for the dye by the amyloid that is present It is positive in less than half of the primary cases and is usually equivocal. Another objection to the use of intravenous Congo red is that it is not entirely safe It should be used with caution in elderly individuals and in patients who have previously received the dye. Schkoff and Bernstein reported six serious systemic reactions, with two fatalities, in 100 consecutive cases in which the intravenous dye was used All patients with severe reactions had received the dye previously without reaction It also should be used with caution when the skin is involved, and perhaps should not be used at all when skin involvement is extensive or in exposed surfaces because of the possibility of stubborn, fiery-red staining of the tissues

Bennhold considered 60 per cent removal of the dye from the serum between 4-min and 60-min samples presumptive evidence of systemic amyloidosis. Because false-positive results occasionally appear, several investigators have modified Bennhold's technique, but none of the modifications have eliminated the basic criticism that variable amounts of the dye are absorbed by nonamyloid tissues, thereby making impossible the diagnosis of amyloid in the tissue in minimal or early cases To eliminate false-positive results, the criterion of 90 to 100 per cent removal of the dye in the 1-hr sample has been suggested Unger et al removed specimens at 2- or 4-min and 30-min intervals, and considered removal of 35 per cent of the dye between the 2- or 4-min and 30-min specimens as presumptive evidence of amyloidosis

The intravenous Congo-red test is of more value in the secondary type of amyloidosis because of more frequent and often more extensive liver involvement The test also is likely to be more positive in secondary amyloidosis because of the much greater affinity of the amyloid tissue for the dye in this type of the disorder.

Local injections of Congo red may be used when mucous membrane or skin lesions are present It is a useful test, but tissues may not take the dye up readily in primary cases. Here too, it must be remembered that skin discoloration may persist.

TISSUE BIOPSY. Biopsy of the involved tissue is the only certain diagnostic measure It is also of special value in those cases with skin involvement because it avoids the danger of persistent staining. Biopsy occasionally may be falsely negative because the particular section taken does not happen to contain amyloid material and, in the primary systemic type, because of lack of affinity of the amyloid tissue for the various amyloid stains. Biopsy of the tongue, mucous membranes, striated muscles, skin, tendons, liver, and even the stomach have yielded positive and diagnostic results in primary systemic amyloidosis. Biopsy of the liver and spleen in the secondary type have occasionally been diagnostic. Needle biopsies of the liver were positive in seven cases thought to have primary systemic amyloidosis (Pruitt et al., 1953). Unfortunately, differences between the primary and secondary forms are not always clear-cut, and Pruitt et al. mentioned this. Because of one reported case of fatal hemorrhage from the liver following liver biopsy, Pruitt et al advise that, if congestive failure is evident, appropriate treatment should be carried out for several days before the liver biopsy in order to reduce the venous pressure as much as possible.

Schkoff and Robitzek performed gingival biopsies on 47 patients with secondary amyloidosis without gross evidence of gingival involvement. Biopsies were positive in 14 of 18 patients in whom the diagnosis of amyloidosis could be made with reasonable certainty. These authors recommended biopsy of gingival tissues because of their accessibility, the simplicity of the technique; the resistance of the tissues to infection; and the freedom from danger of severe hemorrhage.

Because cardiac amyloidosis may occasionally simulate chronic constrictive pericarditis (Maxwell and Kimble, Gunnar et al) and pericardiectomy might be contemplated, Josselson et al. (1952) suggested *myocardial biopsies* in these cases before pericardiectomy is done Sections of the left atrial appendage were studied in 11 of their 29 cases of amyloidosis localized in the heart, and amyloid was found in 7 of the 11 cases.

ELECTROCARDIOGRAM. The electrocardiogram is usually abnormal when amyloid deposits are present in the heart, but changes are *nonspecific*, although the particular findings may be suggestive when considered with the rest of the picture. Wessler and Freedburg presented two cases, and analyzed the electrocardiograms in nineteen published cases in which the electrocardiograms were recorded Their two cases showed definite Q waves in the precordial leads suggestive of anterior myocardial infarction. An autopsy on one of these patients showed amyloid deposits but no infarct, fibrosis, or narrowing of the coronary vessels. No uniform pattern was elicited, but all electrocardiograms were abnormal. There was prolongation of the P-R interval in six patients, low voltage of the QRS complexes in the standard limb leads in twelve, deep Q waves in the precordial leads in two, and P-

low temperatures, showed any significant effect in preventing development of amyloidosis in albino mice. The author suspects that liver is not helpful in most cases, because others have reported failures with its use and most authors have not mentioned its use in their own cases, although many have referred to Grayzel's favorable results

THE HEART IN AMYLOIDOSIS COMPLICATING MULTIPLE MYELO

The heart is not involved in multiple myeloma unless this disease is complicated by amyloidosis, this apparently occurs in about 15 per cent of the cases (Bayrd and Bennett). Magnus-Levy (1933) reported 35 instances in 150 cases, and Snapper et al. reported 8 instances in 41 autopsied cases

Justifiably all authors on the subject of amyloidosis have classified amyloidosis in multiple myeloma separately. Although amyloidosis is secondary to multiple myeloma, it has the characteristics of primary systemic amyloidosis

ETIOLOGY AND PATHOGENESIS

The basic cause of both diseases is unknown. The most favored theory for the pathogenesis of amyloidosis is that it is related to hyperglobulinemia (Magnus-Levy; Reimann et al) because of their coexistence in experimental animals and in many diseases, especially multiple myeloma Magnus-Levy (1952) thinks that amyloidosis and multiple myeloma are disturbances of protein metabolism and originate in the plasma cell

PATHOLOGICAL PICTURE

The pathological picture of amyloidosis, especially in relationship to the heart and blood vessels, is discussed in detail earlier in this chapter.

Amyloidosis secondary to multiple myeloma has the atypical anatomic distribution and the atypical staining reactions of primary systemic amyloidosis Occasionally, amyloid will form intraosseous tumors, at times obscuring the underlying plasmocytoma within which it arises The digestive tract was involved in seven and the heart in five of eight autopsied cases of amyloidosis complicating multiple myeloma (Snapper et al.)

The bones most commonly involved in multiple myeloma are cancellous bones with considerable red bone marrow, especially flat bones such as the ribs, sternum, clavicle, skull, and pelvis, and the vertebrae and proximal ends of the femur and humerus Classically, ..crete lesions occur in the flat bones, but diffuse demineralization is more common. Pathological fractures, especially compression fractures of the vertebrae, are common. Geschicter and Copeland found nephritis in 86 per cent of the kidneys examined.

Of 30 consecutive autopsies at Mount Sinai Hospital, 73 per cent were found to have diffuse or nodular infiltration of the liver, spleen, and lymph nodes with myeloma cells.

CLINICAL DESCRIPTION

Patients with multiple myeloma usually seek medical advice because of skeletal symptoms Major complaints in order of frequency, alone or in combination, are pain, especially of back and thorax, weight loss, pathological fractures, and palpable tumors of superficial flat bones (Lichtenstein and Jaffe).

The onset is often insidious, but occasionally the onset is sudden, especially with bone fracture or collapse of a vertebra. Oddly, in amyloidosis complicating multiple myeloma, the incidence of bone pains and of bone lesions seen on roentgenography becomes less frequent Five of eleven patients with amyloidosis had no roentgenographic evidence of bone involvement and only one of these had significant bone pain (Snapper et al.). Signs and symptoms of neuritis appeared in 40 per cent. Bleeding tendencies were mentioned by several authors Snapper et al. noted hemorrhagic tendencies in 35 per cent. Renal involvement is common and occasionally severe Geschicter and Copeland found 61 per cent to have Bence Jones proteinuria In the series studied by Snapper et al , 13 of 41 cases autopsied showed microscopic pathology of myeloid kidney; nine of these died in severe uremia. The blood pressure is usually normal, even in the presence of uremia, a phenomenon which helps confirm the impression that the myelomatous kidney is nonhypertensive. Of 97 patients, palpable hepatomegaly was present in 40 per cent and hepatosplenomegaly was present in 23 per cent. The liver was smooth, firm, and usually nontender. The lymph glands were less frequently enlarged, and usually only moderately

Primary Systemic Amyloidosis. When similar cardiac findings are associated with signs or symptoms of involvement of other organs, *diagnosis is* possible and *amyloidosis* often should be suspected. When other organs are involved, other causes for their involvement naturally should be considered. Macroglossia, which occurs in 40 per cent of amyloidosis cases, is important because it is uncommon otherwise. Cirrhosis of the liver should be considered when ascites occurs, especially when associated with jaundice. The general opinion is that the liver and spleen are not commonly involved; however, Higgins and Higgins found clinical involvement in these organs in 60 per cent of 23 cases. When the liver is enlarged due to amyloid deposits and not congestive failure, *it is hard and not tender.* When liver function is disturbed, liver function tests are usually more abnormal than one would expect *from congestive failure alone, suggesting* primary hepatic disease. Jaundice may occur and attract attention to liver disease, especially in the primary form, in which it has been reported six times (Dahlin, 1949) Needle biopsy of the liver may be negative in the presence of amyloidosis with hepatomegaly, but is likely to be positive Renal involvement with the nephrotic picture occurs in about one-third of the cases When the nephrotic picture is associated with myocardial failure, the edema may be greater than might be expected from the nephrosis alone, and the albuminuria is often greater than one would expect from congestive failure alone Occasionally azotemia reveals the existence of organic renal disease

Digestive tract symptoms may be vague or bizarre, and, without evidence of involvement elsewhere in the body, diagnosis of amyloidosis is difficult The digestive tract was involved in 25 of 54 cases reported by Dahlin (1950). Many of these patients had no symptoms referable to the digestive tract, but five had serious hemorrhage and three simulated carcinoma of the stomach Gastric ulcers were reported in three cases (Lindsay) Rarely, there is clinical evidence of intestinal obstruction due to infiltration of the intestinal wall without obliteration of the intestinal lumen Adrenal hypofunction may be suspected because of muscular weakness, but other findings consistent with adrenal hypofunction are rare, especially in the primary type. *Myasthenia gravis is readily ruled out.* Joint involvement with limitation of motion and occasional pain in extremities may simulate arthritis. Muscle or tendon biopsy may confirm the diagnosis. Various skin diseases may be suspected, and with ecchymoses, petechiae, and scleroderma-like lesions, one should suspect some systemic disease.

In cases simulating chronic constrictive pericarditis, careful search for evidence of other organ involvement may be fruitful The clinical pattern of intractable heart failure with macroglossia (present in 40 per cent of the cases), general muscular weakness (50 per cent), and weight loss (40 per cent), with or without other clinical evidence should give one a clue as to the diagnosis as well as *differentiate the primary* from the secondary form. Other clinical combinations also should be suggestive and any additional clinical evi*dence should make the* diagnosis relatively easy if one just thinks of the disease

In the *secondary form,* the heart is involved *in about 10 per cent of the* cases Nonresponsive heart failure, developing in a patient with one of the common inciting diseases, should arouse suspicion of *amyloidosis,* with or without evidence of further organ involvement.

With renal involvement, *albuminuria* is usually greater than with congestive failure alone.

PROGNOSIS

Primary amyloidosis is 100 per cent fatal In Eisen's series, the average duration of the disease after the onset of symptoms was 32 months; the longest duration was 14 years After the onset of symptoms in the secondary form, 82 per cent succumbed within 1 year (Eisen); however, a few cases have been known to recover after removal of the inciting cause.

TREATMENT

Treatment of primary amyloidosis is *purely* symptomatic and directed at complications

Treatment of secondary amyloidosis is primarily directed at removal of the *inciting disease,* however, powdered whole liver may be helpful Grayzel et al. (1938) reported relief with the use of 4 to 8 Gm of powdered whole liver daily. After using 14 different preparations, Grayzel et al. (1956) found that only powdered whole liver, desiccated at relatively

ated by electrophoretic separation or Howe fractionation.

In metastatic carcinoma, bone lesions are usually not so clear-cut and often show osteoblastic changes, and the serum alkaline phosphatase is often elevated. Skeletal demineralization in senile osteoporosis is usually limited to the spine and pelvis In hyperparathyroidism, serum calcium and alkaline phosphatase are increased and the serum phosphorus is decreased.

PROGNOSIS

Multiple myeloma is 100 per cent fatal, and the downhill progress may be hastened if amyloidosis appears, especially if it involves the heart. When Bayrd and Bennett reported their series of 66 patients, 55 had died. The shortest survival period after the onset of symptoms was 1 month and the longest 24 months, with an average of almost 19 months.

TREATMENT

Treatment is primarily symptomatic. Radiotherapy gives some palliative relief, especially when pressure symptoms occur, and administration of stilbamide, urethane, ACTH and cortisone may be followed by periods of wellbeing, but the general course of the disease remains unchanged.

so. Weakness is common, and emaciation is frequent in advanced stages.

Five of eight autopsied cases with amyloidosis complicating multiple myeloma revealed *cardiac involvement*, and four of these died of congestive failure (Snapper et al.). Four of the eight cases died in uremia; of these three had myelomatous kidneys and the fourth had a combination of myelomatous kidneys and amyloidosis. Only one of the eight patients had hypertension, and he did not die of uremia. Ten per cent of the patients with amyloidosis in multiple myeloma have macroglossia (Bayrd and Bennett).

LABORATORY STUDIES

Roentgenographic Examination. Two types of bone lesions are recognizable on roentgenograms in multiple myeloma: (1) typical, multiple, discrete, lytic lesions without bone production, especially in the flat bones, and (2) diffuse demineralization, especially in the vertebrae. Bone lesions may be absent, and this is especially true if amyloidosis is present.

Urinalysis. Bence Jones proteinuria, a most significant finding, is present in about 50 per cent of the cases, but may be present at one time and not at another. A 24-hr specimen will sometimes be positive when isolated specimens are negative.

Blood Studies. Snapper et al found in 97 consecutive cases of multiple myeloma that the *total serum protein level* was above 8 Gm/100 ml in 72 per cent of the cases In 45 per cent of these, the serum globulin exceeded 7 Gm/100 ml. *Albuminemia* was found in all cases studied

In *blood serum* studies, calcium is often elevated, inorganic phosphorus is usually normal, except in the presence of uremia when it is high, alkaline phosphatase is usually normal, except in the presence of fractures when it may be elevated, and uric acid is commonly elevated. Serum uric acid was above 4 mg/100 ml in 87 per cent of the patients (Snapper et al).

Electrophoretic studies are helpful in differentiating the various protein fractions of the serum. Gamma globulin predominates in multiple myeloma.

In multiple myeloma, *peripheral blood studies* reveal moderate to severe normocytic, hypochromic anemia as one of the most common findings The leucocyte count is variable. Plasma cells are usually elevated, and should be looked for carefully. Excessive rouleaux formation occurs in over half of the patients.

A rapid erythrocyte *sedimentation rate* is characteristic; however, 10 of 97 consecutive patients had normal sedimentation rates, and none of them had elevated serum globulin levels (Snapper et al.).

DIAGNOSIS

Diagnosis of amyloidosis in multiple myeloma is intriguing. The first essential is to think of these diseases, especially in bizarre cases Amyloidosis should be looked for carefully in all cases of multiple myeloma, and vice versa. Amyloidosis occurs in about 10 per cent of the patients with multiple myeloma, and the latter is not an uncommon cause of the picture of primary systemic amyloidosis. Amyloidosis should be suspected in all cases of multiple myeloma in which there is congestive heart failure or macroglossia, neither of which occur in uncomplicated multiple myeloma. With amyloid involvement of several muscles, tendons, and joints, rheumatoid arthritis may be suspected.

Clinically, pain, especially back or rib pain, weakness, tumors of superficial flat bones, hyperproteinemia, especially hyperglobulinemia, and punched-out osteolytic bone lesions or compression of vertebrae, alone, but especially in combination, should cause one to check further for multiple myeloma However, it should be remembered that bone pains and bone lesions seen on roentgenography are much less frequent when amyloidosis complicates multiple myeloma

Hypercalcemia, an elevated serum uric acid, uremia without hypertension, albuminuria, hepatosplenomegaly, and unexplained anemia, fever, or hemorrhagic tendencies should also cause one to consider multiple myeloma. If Bence Jones proteinuria, which occurs in 50 per cent of the cases, is present, multiple myeloma is almost certain. Myeloma cells in bone-marrow biopsies, of course, are diagnostic Fortunately, most patients will have Bence Jones proteinuria or hyperglobulinemia; however, hyperglobulinemia is less pathognomonic, because it occurs in other diseases such as acute lupus erythematosis, cirrhosis of the liver, kala-azar and other diseases If necessary, the globulins in these diseases can usually be differenti-

is the primary site of the malignancy. A similar behavior is shown by primary pericardial sarcoma and myxofibrosarcoma.

Myocardium. Rhabdomyoma and sarcoma are the two most common myocardial tumors. In contrast to sarcoma, which is mostly seen in aged persons, well over one-half of the rhabdomyomas occur in individuals under 1 year of age.

The term *rhabdomyoma* is a misnomer firmly fixed in the literature. Sussman and Stasney have termed the process "congenital glycogenic tumor of the heart." Since it has been convincingly proved that the condition results from a separation or a focal arrest in maturation of striated muscle during embryonic development, this term fits well into the concept of a dysontogenetic process.

Of the 69 cases analyzed by Kidder, over 50 per cent were associated with other anomalies (harelip, cleft palate, sebaceous gland adenomas, cysts and tumors of the kidneys, and so on), the most common being tuberous *sclerosis.* Steinbiss has explained the frequent association of rhabdomyomas with tuberous sclerosis on the assumption of an excess of glycogen in the brain and heart *blastemas.*

Fifty-two per cent of the patients with cardiac rhabdomyoma die in the first year of life and 86 per cent before they reach puberty. The youngest patient on record was a 6-month fetus, the oldest, a 45-year-old man. Males and females are almost equally affected, with a slight predominance in the male (60 per cent). The absence of any appreciable racial predilection is indicated by observations in Negroes and Japanese. Any portion of the heart may be involved by the condition, including the valve leaflets, in the majority of cases several noncapsulated, soft, discrete, yellowish-white nodules are found. A single, coarsely fasciculated nodule, grossly resembling a fibroma, was present in one case.

The most prominent histological characteristic of the nodule is the so-called "spider cell," characterized by a large nucleus suspended by threads of cytoplasm between large vacuoles. Von Recklinghausen, in the first case report, considered the vacuoles to be dilated lymph spaces. Virchow also conceived that the content of the vacuoles was either lymph or serous fluid. The glycogenic component of the "spider cell" was suggested by Seiffert and proved by Wolbach. Since the myofibril passes through a "spider-cell phase" during development, it is quite obvious that the rhabdomyomatous nodule represents a focal arrest in the maturation of cardiac muscle fibers. Along this line, a possible relationship between cardiac rhabdomyoma, "congenital" hypertrophy of the heart, and von Gierke's disease has been suggested.

As commonly applied, the term *hamartoma* designates a tumor resulting from arrested development of elements normally present in the organ where the tumor is found. In addition to myofibrils, fibrous tissue, blood vessels, nerves, and fat enter in the composition of the heart. Any of these tissues can be the potential source of developmental error or tumor growth in a true sense. Since the two conditions are often difficult to differentiate, they may be conveniently considered together. Fibroelastic, fibrolipomatous, fibromatous, and lipomatous growths have been described. Intramyocardial hemangiomas and lymphangiomas have also been recorded. "Epithelial inclusion cysts" have been variously interpreted as arising from sequestration of cells of the foregut or from metaplasia of mesodermal elements.

Primary malignant tumors of the myocardium are less common than benign tumors, the ratio being estimated as about 1:16. Myofibrils have little, if any, regenerative power, and this fact explains the extreme rarity of primary malignant muscle tumors. Nine such cases have been reported in the literature, characterized mainly by the straplike shape of the cells, strongly acidophilic cytoplasm, formation of syncytial strands, and sporadically by the presence of large vacuolated giant cells and by striations within the neoplastic cells.

The sarcoma group of more frequent occurrence runs the gamut of mesenchymal tumors: fibrosarcomas, fibromyxosarcomas, myxosarcomas, lymphosarcomas, reticulum-cell sarcomas, leiomyosarcomas, round-, spindle-, and mixed-cell sarcomas; 143 of these had been described up to 1955. *Kaposi's disease* of the heart has also been recorded. The great variety of diagnostic terms used by the individual authors reflects the uncertainty of the criteria that are to be met in any attempt at classifying the connective tissue growths in general.

The symptom complex of myocardial sar-

PATHOLOGICAL ASPECTS

Boneti (1679) and Morgagni (1761) have both been credited with descriptions of primary tumors of the heart. In the following two centuries, several hundred cases have been slowly accumulated and, in a review of the world literature, Mahaim gathered 413 primary growths of the heart and pericardium

Although it is generally agreed that primary tumors of the heart occur rarely, data on their actual frequency vary considerably Assuming all cases to have been reported, incidence ranges from 0 33 per cent, in the Pollia and Gogol review of 46,072 autopsies, to 0 0017 per cent in the National Survey of 480,331 autopsies between 1938 and 1942.

New interest is being injected into this subject by sporadic reports of cases in which the condition was diagnosed during life and successfully corrected by means of surgery. Since at least some of the cardiac tumors are amenable to surgical treatment, their recognition during life ceases to be of purely academic interest. Twelve cases are already on record in which diagnosis in the living patient was made possible by the recognition of malignant cells in the pericardial fluid examined by cytological method.

The classification proposed by Mahaim of *polypoid* and *nonpolypoid tumors* has diagnostic and probably therapeutic merit, but it lumps together a wide variety of conditions and includes lesions which, in the strict sense of the word, are not true tumors. Since a consideration of the cell types is of importance, a subdivision into pericardial, myocardial, and endocardial tumors perhaps lends itself to a better understanding of the histogenetic element

PRIMARY TUMORS

Pericardium. At the time of the report of Hochberg and Robinson (1950) describing the successful removal of a large cavernous hemangioma in an 8-year-old girl, 97 observations of primary pericardial tumors had appeared in the literature, mostly *fibromas, angiomas,* and *lipomas* The occurrence of tumors of smooth muscle, a normal component of the pericardium, has also been reported. An intrapericardial cystic teratoma was removed surgically by Beck Incidental to the discussion of tumors springing from lymphatic endothelium, the author (1935) mentions the occurrence of pericardial lymphangioendotheliomas, but others confronted with a similar neoplasm felt that serosal lining cells were a more probable origin and termed the growth *mesothelioma* The concept that this particular type of tumor arises from surface mesothelial cells is now more favorably accepted A wide morphological variation may be exhibited by the pericardial mesothelioma. In general the growth involves large portions of the pericardium and extends early into the adjacent myocardium and even into distant organs When this occurs, it may be difficult to decide which

endocardium, and pericardium may be involved, singly or in combination Leukemic cells are present within the blood capillaries and in the interstitial tissue between the myocardial fibers Actually, the concept of myocardial involvement should be restricted to cases in which leukemic cells are seen outside the lumens of the blood channels The infiltrate may be so scanty as to be detected only under the microscope, or so abundant as to give rise to grossly visible masses A case is on record in which death occurred following rupture of the left atrium, secondary to infiltration of myelogenous cells

Setzu in 1942 was able to gather ten instances of myocardial Hodgkin's disease from the literature and reported an additional case of his own Subsequently, Rast et al. recorded a case with grossly visible involvement of the pericardium by numerous grayish-white nodules, the mediastinum was also involved. Extension of the disease from the mediastinum into the pericardium and myocardium is not rarely seen in routine post-mortem material, and the small number of reported cases does not reflect the actual frequency with which involvement of the myocardium occurs in this condition.

Metastatic Tumors. Metastatic tumors occur from twenty to forty times more frequently than primary malignancies, with an estimated incidence of 3 9 per cent Strong kneading action, rapid blood flow, restricted lymphatic connections, and the metabolic peculiarities of the striated muscle are probably the main features which operate in minimizing the incidence of cardiac metastasis. The relative avascularity of the cardiac valves further explains the rarity of the involvement. All major organs and practically all types of malignancies have been reported as sources, and invasion may occur by embolic, lymphatic, and direct-extension routes. In only one instance was the heart the sole organ involved. (Embolic tumor cells from a primary lung carcinoma were found in the coronary arteries.)

The morphologic aspects of the metastatic nodules are similar to those of similar nodules of other organs and, with the exception of cancerous melanoma, there are no features permitting identification of the primary site from the appearance of the cardiac metastasis. Breast carcinomas, lymphomas, malignant melanomas, and lung carcinoma lead the list of the primary sources in the order given. Yater has found that the right side of the heart is more frequently affected, and Pritchard quoted Kretz's experiment on coronary arterial flow as an explanation of the higher opportunity of embolic tumor cells to lodge on the right than on the left. However, Herbut and Maisel, in a series of 35 cases, found an almost equal distribution of metastatic growths on both sides while, in a series of 101 cases (Scott and Garvin), left-sided involvement was seen to prevail Implantation of tumor cells in the endocardium is rarely mentioned in the literature However, in the series reported by Young and Goldman, there are several instances of myocardial metastasis ulcerating through the endocardium and implanting within the chambers.

CLINICAL ASPECTS

FREQUENCY

Like all bizarre uncommon diseases, tumors of the heart or pericardium are quite unimportant until they become yours to appraise. And, to the afflicted, the lesion is "common" and all-significant Further, because cardiac or pericardial tumors appear but infrequently, it does not follow that they occur "accidentally," i e, without cause Since no physician is likely to see enough of these lesions during the normal course of his observational years, minutely detailed recorded observations on each case encountered are essential for the compilation of data adequate for valid analysis (Table 16-1).

Basic classification is possible in a number of ways (1) primary or secondary lesion, (2) benign or malignant, (3) solid or cystic, and (4) according to site of origin. Detailed histopathologic examination provides the only method of assessing the ultimate behavior of these tumors.

Commonly, *tumors of the breast, of the genitourinary system,* and *of bronchogenic origin* metastasize to the heart or pericardium.

coma, i.e., cardiac enlargement together with superior-vena-cava–obstruction syndrome, arises chiefly from the frequent location of the growth in the right atrium. In the series of cases reviewed by Mahaim, over half of the sarcomas arose in the right side of the heart, almost equally distributed between the right atrium and the right ventricle. The size of the organ is in general markedly increased, either by massive infiltration or more often by polypoid growths projecting into the chambers. (In one case the heart weighed 2,700 Gm.) As the pericardium becomes involved and the growth extends into adjacent structures, the primary source of the malignancy can no longer be established with certainty.

Endocardium. Endocardial growths constitute nearly 50 per cent of the primary cardiac tumors, but several conditions generally included in the group are not tumors in the true sense. This applies to the so-called hematonodules (blood cysts), a common anatomical finding in the heart valves of infants, which lack pathological significance and are variously considered to be telangiectases or extravasations of blood into the substance of the semilunar cusps or AV leaflets.

Small, villous, comb- or tassel-shaped excrescences of fibroelastic tissue are frequently seen to project on the free borders of leaflets. These formations, known as *Lambl's excrescences,* are not true tumors or even hamartomas. It is generally agreed that they are a manifestation of normal aging, stretching, and wear-and-tear of the collagenous and elastic fibers at the surface of the valvular endocardium.

Endocardial myxoma of the atria (and less frequently of the valves) is the most common primary neoplasm of the heart. Roughly 75 per cent of the 200 cases reviewed by Brewin were in the left atrium and 25 per cent in the right atrium. In almost every instance the growth arises in the region of the fossa ovalis, or its rim, as a pedunculated, lobular, polypoid or villous mass with smooth, glistening surfaces. Constistency may vary from gelatinous to rubbery, and color from yellow-gray to light brown with occasional areas of hemorrhagic discoloration. The microscopic picture is that of a groundwork of amorphous, finely granular or fibrillar material which may or may not stain with mucin stains. A layer of flattened endocardial cells is almost always recognizable at the surface of the mass and a variable number of lymphocytes, plasma cells, and fibroblasts are scattered in the myxomatous tissue. Stellate cells, giant multinucleated cells, delicate blood channels, scattered erythrocytes, hemosiderin and hematoidin pigment are associated microscopic features. Opinions are divided as to whether these tumors are true myxomas or organized thrombi.

Emboli of myxomatous tissue have been found in the extremities, aorta and renal arteries, lungs, and brain. Ribbert has tried to explain the frequent localization of these tumors in the region of the fossa ovalis as evidence of their origin from remnants of myxoid tissue of the embryonic endocardium, but Pritchard, who undertook examination of the interatrial septum in 53 unselected hearts, failed to demonstrate any such remnant.

Since the evidence for or against the neoplastic nature of this peculiar condition is far from being conclusive, the inclusive classification proposed by Husten into (1) end stage of organized thrombus, (2) true myxoma, and (3) doubtful lesion, either thrombus or myxoma, still has its place. All instances the author has encountered seemed to fit in the last category.

Endocardial fibromas are also on record, but since they lack distinctive characteristics, difficulties may arise in differentiating them from organized vegetations or *Lambl's excrescences*

METASTATIC AND SYSTEMIC NEW GROWTHS

Leukemia and Allied Conditions. Although the nature of leukemia and allied diseases is not yet clearly understood, the underlying disease process is that of a fatally progressive, invasive growth of immature cellular elements, from which the myocardium does not escape The myocardium is involved in leukemia more frequently than previously assumed. In a series of 123 fatal cases (Kirschbaum and Preuss), the myocardium was found to display leukemic involvement in 34 per cent of the cases, with the highest incidence (61 per cent) in the stem-cell category. A comparable frequency (36 per cent) was noted by Saphir among 95 leukemias of various kinds. Myocardium,

endocardium, and pericardium may be involved, singly or in combination. Leukemic cells are present within the blood capillaries and in the interstitial tissue between the myocardial fibers. Actually, the concept of myocardial involvement should be restricted to cases in which leukemic cells are seen outside the lumens of the blood channels. The infiltrate may be so scanty as to be detected only under the microscope, or so abundant as to give rise to grossly visible masses A case is on record in which death occurred following rupture of the left atrium, secondary to infiltration of myelogenous cells

Setzu in 1942 was able to gather ten instances of myocardial Hodgkin's disease from the literature and reported an additional case of his own Subsequently, Rast et al. recorded a case with grossly visible involvement of the pericardium by numerous grayish-white nodules, the mediastinum was also involved Extension of the disease from the mediastinum into the pericardium and myocardium is not rarely seen in routine post-mortem material, and the small number of reported cases does not reflect the actual frequency with which involvement of the myocardium occurs in this condition.

Metastatic Tumors. Metastatic tumors occur from twenty to forty times more frequently than primary malignancies, with an estimated incidence of 3 9 per cent. Strong kneading action, rapid blood flow, restricted lymphatic connections, and the metabolic peculiarities of the striated muscle are probably the main features which operate in minimizing the incidence of cardiac metastasis The relative avascularity of the cardiac valves further explains the rarity of the involvement. All major organs and practically all types of malignancies have been reported as sources, and invasion may occur by embolic, lymphatic, and direct-extension routes. In only one instance was the heart the sole organ involved (Embolic tumor cells from a primary lung carcinoma were found in the coronary arteries.)

The morphologic aspects of the metastatic nodules are similar to those of similar nodules of other organs and, with the exception of cancerous melanoma, there are no features permitting identification of the primary site from the appearance of the cardiac metastasis Breast carcinomas, lymphomas, malignant melanomas, and lung carcinoma lead the list of the primary sources in the order given. Yater has found that the right side of the heart is more frequently affected, and Pritchard quoted Kretz's experiment on coronary arterial flow as an explanation of the higher opportunity of embolic tumor cells to lodge on the right than on the left. However, Herbut and Maisel, in a series of 35 cases, found an almost equal distribution of metastatic growths on both sides while, in a series of 101 cases (Scott and Garvin), left-sided involvement was seen to prevail Implantation of tumor cells in the endocardium is rarely mentioned in the literature. However, in the series reported by Young and Goldman, there are several instances of myocardial metastasis ulcerating through the endocardium and implanting within the chambers.

CLINICAL ASPECTS

FREQUENCY

Like all bizarre uncommon diseases, tumors of the heart or pericardium are quite unimportant until they become yours to appraise. And, to the afflicted, the lesion is "common" and all-significant. Further, because cardiac or pericardial tumors appear but infrequently, it does *not follow* that they occur "accidentally," i e., without cause Since no physician is likely to see enough of these lesions during the normal course of his observational years, minutely detailed recorded observations on each case encountered are essential for the compilation of data adequate for valid analysis (Table 16-1).

Basic classification is possible in a number of ways (1) primary or secondary lesion, (2) benign or malignant, (3) solid or cystic, and (4) according to site of origin. Detailed histopathologic examination provides the only method of assessing the ultimate behavior of these tumors.

Commonly, *tumors of the breast, of the genitourinary system,* and *of bronchogenic origin* metastasize to the heart or pericardium.

TABLE 16-1. INCIDENCE OF CARDIAC TUMORS

Walker	University of Michigan	..	.	1	11,101

Nasopharyngeal and esophageal carcinomas, as the author's studies with Maloney and von Fraenkel have verified, metastasize frequently to the heart or pericardium. *Malignant melanomas* often transplant to the intramediastinal structures Half of the victims of *leukemia* disclose infiltrative lesions of the heart or pericardium.

Secondary malignant lesions may be discovered in any part of the heart or pericardium but the endocardial areas seem somewhat less prone to invasion

Carcinoid tumors of the gastrointestinal tract are frequently associated with cardiovascular abnormalities Pulmonic or tricuspid valvular endocardial lesions, ostensibly acquired, are typical accompaniments. Rambo and others have elaborated upon this relationship

CLINICAL RECOGNITION

Tumors of the heart tend to be diagnosed by exclusion. Barring some prominent roentgenographic or clinical manifestations, suspicion of their presence should be deferred until more common causes of cardiovascular disease have been considered. While it is of personal satisfaction to the physician to have diagnosed accurately such an unusual disease, scores of more frequent lesions should not be overlooked Sooner or later, one can always diagnose a cardiac tumor if he is constantly on the alert

Symptoms. Discomfort in the chest may range from *precordial aching* to *painful distress*. A sense of fullness may be experienced in the mediastinum or thorax. Cardiac *palpitation* may occur. *Dyspnea*, with or without heart failure, is not uncommon. If heart failure is present, it tends to be progressive and refractory even to intensive diuretic management. Appearance in a younger individual (up to age 40) of sudden unexplainable heart failure, possibly with some atypical associated findings, can be the initial evidence of cardiac tumors. Intermittent, otherwise inexplicable heart failure, *venous engorgement* of face and neck, and *cyanosis* or *dyspnea*, may be due to the ball-valve action of an obstructive pedunculated intracardiac neoplasm. Such a lesion often causes *syncope, convulsions*, or *coma* because of the significant degree of cerebral insufficiency.

Heart murmurs are sometimes produced by tumors of that organ. In almost all instances, these are due to a *pedunculated* neoplasm, regardless of whether it exerts a ball-valve action Otherwise, gross deformity of normal cardiac chambers is necessary to produce an actual murmur. Distortion of an annulus, a valve, or the entire perivalvular region may result from an extensively infiltrating lesion

Characteristically, the murmur is heard best in the mitral area, but this is by no means universal Variability of its intensity, quality, or pitch would favor the idea of pedunculation, especially if this occurs regularly with *postural changes*. Myxomas of the left atrium most commonly mimic the auscultatory abnormalities of mitral stenosis. This imitation even extends to ballistocardiographic records. Despite painstakingly detailed histories and the employment of all advanced methods of cardiopulmonary diagnosis, there are times when a myxoma of the left atrium has led to the erroneous diagnosis of rheumatic mitral valvular stenosis. In effect, of course, a "stenosis" may be present functionally.

Some authors have indicated that, in one of their patients with an intracavitary atrial tumor, auscultatory signs of mitral stenosis were pres-

ent when the patient was erect and were changed to those of mitral insufficiency when the patient reclined.

Bailey et al. report a patient who had "attacks of dyspnea, paroxysmal tachycardia, and coughing *which were relieved by lying down.*"

While severe prolongation of obstruction of peripheral circulation may progress from intense cyanosis to focal necrosis of the toes, fingertips, or nose, *gangrene* may also develop, or the individual may suffer unexpected *sudden death.* Cardiac tumors with long peduncles are apt to reproduce startling symptoms and signs upon changes in the patient's posture *Morgagni-Stokes-Adams episodes* are apparent at times

Signs. DISTURBANCES OF HEART RATE OR RHYTHM Paroxysmal alterations of heart rate or rhythm occasionally may reveal the presence of a cardiac tumor Similarly, variations in AV or intraventricular conduction can herald neoplastic disease of the heart Sudden and rapid alterations of existing or dominant rhythm, or of conduction are suggestive signs

ENDOCARDITIS A clinical picture *simulating* subacute bacterial endocarditis, but without positive blood cultures, affords a *situation in* which the diagnosis of tumor of the heart should be entertained. Of course, the possibility of lupus erythematosus, collagen disease, amyloid lesions, and the like must also be eliminated.

Electrocardiography. There are no electrocardiographic abnormalities pathognomonic of tumors of the heart or pericardium If ECG variants are found in a patient suspected of having either a primary or a metastatic tumor of the heart or pericardium, the problem of ascribing it to the neoplastic process is often difficult, particularly if the individual is of an age group in which coronary artery disease is probable, or if he has any *evidence of* any organic cardiovascular disease. It is probably safe to assume that an ECG diagnosis of tumor is made exclusively by elimination Unless "strategic" areas of the heart are involved, furthermore, it is not improbable that the ECG would provide no information at all relative to the neoplastic process This is especially true if there are sporadic metastatic nodules in either the myocardium or the pericardium

An unequivocal separation of the ECG tracing of coronary artery disease from that produced by neoplasm represents the most frequently encountered "specific" differential diagnostic problem The ECG inscribed by the neoplastic heart particularly mimics that of coronary artery disease, and especially myocardial infarction. Assessment of the total clinical problem is, therefore, imperative. Appearance of bizarre S-T segment or T-wave aberrations is possible supportive evidence for a diagnosis as unusual as this.

Disturbances of heart rhythm occur as unpredictably with neoplasm of the heart and its protective sac as do the areas of new tissue formation or metastatic implantation. Critical location of the lesions implies instigation of deviant rhythms, whether unimportant in type or potentially lethal in character. So, the gamut from a wandering pacemaker to ventricular fibrillation may be encountered. Details of abnormalities of heart rhythm may be found elsewhere.

Conduction abnormalities also may be produced by the neoplastically diseased heart. Again, as with rhythmic alterations, the site and kind are determined solely by chance Elaboration of the exact findings indicative of the several types of conduction disturbance is to be found in the section dealing in detail with that subject.

Roentgenography. X-ray study of the heart is mandatory in making a cardiologic evaluation of an individual. On such film study, primary tumors may be detected, especially if they are extramural Intracavitary growths or margaric nodules certainly escape detection by this method of examination. Infiltrative types of malignancy would tend to remain obscure upon teleoroentgenography of the heart, but preterminally might be recognizable by, among other things, the gross distortion of normal cardiac contours they have caused. Over-all size in the heart sometimes is increased perceptibly by the tumor. Alteration of the intrathoracic position of the heart seldom is produced

Large tumefactions inseparable, even by angiocardiographic techniques, from the heart most probably are tumors of the heart. The author has seen, however, lesions of this type which, upon surgical exploration, proved to be *noncardiac granulomas,* particularly of the Hodgkin's variety. A ragged appearance of the cardiac outline on posteroanterior films of the

heart may indicate an appreciably advanced degree of cardiac tumor formation. These usually are interstitial in type, representing inexorable *sarcomas*. Because of the rarity of this primary tumor of the heart, details of the clinical findings of the sixth hemangioendothelial sarcoma of the heart reported in the world literature and observed personally by the author, are reported here:

CASE REPORT. A 26-year-old white man entered the hospital in severe congestive heart failure, predominantly left-sided. He was extremely dyspneic and irrational, so that the initial history was obtained from his mother. She stated that the patient first complained of chest pain while overseas in 1943 No further record was available concerning this complaint, and apparently the patient got around adequately until January 29, 1948. At that time, he experienced pain across the entire anterior chest and at both scapular angles. He had marked dyspnea, profound weakness, and poor appetite.

He was treated at a nearby hospital for heart failure, and a secondary diagnosis of subacute bacterial endocarditis was made. Sulfonamide therapy, followed by administration of penicillin and streptomycin, was employed with no apparent benefit, although the patient's condition seemingly improved following a short course of the last-mentioned drug His illness continued for 4 weeks and he was then sent home for a brief period before being admitted to Madigan General Hospital on March 2, 1948

On entry there the patient presented marked pallor and obvious dyspnea His lips, tongue, and skin generally were extremely dry and his temperature was 105 2°F. He was mentally disoriented, but passively cooperative

The heart was regular in force, rate, and rhythm, with a sinus tachycardia of 120 per minute There was gross enlargement of the heart, so that the apical impulse was felt in the 6th interspace between the left anterior and midaxillary lines There was a grade 4 coarse and blowing murmur over the pulmonic area, and the 2d aortic sound was markedly accentuated The other valvular areas were normal Arterial blood pressure averaged 110/70 mm Hg supine The lungs revealed coarse rales in both bases posteriorly, especially the left

During this acute episode, he was treated with oxygen, morphine, digitoxin, and mercuhydrin, to which he responded satisfactorily. Five consecutive blood cultures were obtained, following these penicillin was administered in doses of 300,000 units every 3 hr intramuscularly A satisfactory response was obtained within 24 hr but the penicillin was continued for 1 month None of the blood cultures became positive. Blood-pressure readings ranged between 104/70 and 90/60 mm Hg between March 24th and April 8th, the latter readings obtaining from April 3d onward The apical pulse continued at a rate of 130 per minute

Improvement was progressive to a point at which the patient became moderately ambulatory until April 5th. On that date, at 10 o'clock, he became very weak, complained of thirst, and exhibited a violet hue over the upper half of the thorax anteriorly. His face remained pallid, with no cyanosis. The liver was enlarged, extending down 6 to 8 fingerbreadths and filling the entire epigastrium. The patient did not complain of pain He suffered from increased venous pressure. Mercurial diuresis was effective in relieving some of the liver congestion On April 6th, he had an unalleviated acute failure of the right heart, this was unresponsive to protracted energetic treatment, and he died quietly on April 8, 1948

The urine was entirely normal White blood cells varied from 13,250 on admission to 20,150 just before death. The sedimentation rate (Wintrobe method) varied from 42 to 53 mm/hr The hematocrit reading varied from 37 to 44 Nonprotein nitrogen and icterus index were normal

X-ray examination showed a "mitral configuration with marked prominence in the region of the pulmonary arteries and conus" (Fig. 16-5A) Generalized cardiac enlargement was evident

At autopsy the following essential gross findings were seen· The lips were blue A few petechiae were seen over the left anterior chest and the lower sternal region. There was no clubbing of the fingers The nail beds of the fingers were cyanotic and contained no splinter hemorrhages In the peritoneal cavity, there was 600 ml of amber, blood-tinged fluid The left pleural cavity contained 1,000 ml of bloody fluid and the right about 600 ml The left lung weighed 560 Gm, the right 840 Gm. The tracheobronchial lymph nodes were normal The pleural surfaces of both lungs were covered with many round, slightly umbilicated, reddish-purple hemorrhagic nodules 0 5 to 3.5 cm in diameter. All lobes were firm and noncrepitant. Marked congestion was evident and the bronchi exuded hemorrhagic mucus The pericardium was fibrotic and densely adherent to the epicardium, completely obliterating the pericardial sac and averaging 3 mm in thickness The diaphragmatic pericardium was studded with many *purple tumor nodules* averaging 2 5 cm in diameter The heart measured 17 cm transversely, 22 cm vertically, and 11 cm in the anteroposterior diameter With the pericardium, it weighed 2,030 Gm The coronary arteries were small and pliable with marked narrowing of their lumens, no obstruction

was noted The myocardium was firm, dark purple-red, and bloody throughout. There were many *diffuse, confluent tumor nodules* (some centrally necrotic) in all areas but more on the right side and in the upper 1 5 cm of the interventricular septum. Large areas of the endocardium of the right ventricle and atrium and about the tricuspid valve were invaded by the tumor The purple, hemorrhagic, neoplastic nodules had amalgamated the heart and pericardium so that the myocardium was 2 5 cm thick on the right side and 3 cm thick on the left, the outer 2 cm of this side consisted of muscle The wall of the apex of the right ventricle was 5 5 cm thick; that of the pulmonary conus was 4 5 cm thick The distance from the base of the tricuspid valve to the right apex was 7 5 cm, from the base of the mitral valve to the left apex, 8 5 cm The chordae tendineae and papillary muscles were hypertrophied and bloody on section Subendocardial hemorrhages were scattered throughout. The valve circumferences were normal All the tumor nodules were strikingly hemorrhagic and blood had *infiltrated into all the* cardiac tissues. The aorta was normal throughout as were the major aortic and pulmonary branches. The abdominal viscera were congested.

Microscopic findings were as follows. Sections of the lungs showed marked congestion A few small nests of tumor cells were found lying loosely in the parenchyma without any pattern These cells were irregular, with scant eosinophilic cytoplasm and irregular hyperchromatic nuclei Sections of the heart stained with hematoxylin and eosin showed many varying-sized spaces *forming* what appeared to be poorly formed vascular *channels* In many places, these spaces resembled young capillary tubes These channels were lined by a loose network of immature cells resembling endothelium in many places The cells varied in size and shape, had a small amount of pale eosinophilic cytoplasm and hyperchromatic irregular nuclei which had a fine granular network supporting one to three central or eccentric nucleoli. The nuclei filled a large proportion of the cell Some of the nuclear granules were coarse and heavily stained. Some of the cells had phagocytized erythrocytes. Many of these cells were closely grouped, forming thin strands connecting larger ones. Erythrocytes had engorged many vascular spaces to form solid areas of hemorrhage, some of which were centrally necrotic. No striated muscle cells were found in the tumor areas, which had completely *replaced* the myocardium. The section taken from *the left* ventricular wall at the junction of the *tumor tissue* and the myocardium showed the myocardial fibers to be in various stages of *degeneration, with* infiltration of individual tumor cells Here the tumor was sharply delineated from the myocardium There were a few isolated atrophic groups of muscle fibers present in the tumor area. Away from the tumor process, the remainder of the myocardium was *normal*

Fluoroscopy. Evaluation of cardiac *dynamics* is an indispensable part of the heart *examination*. Detection of an extramural myocardial mass may materialize first by this method. The heart tumor should be differentiated from a pericardial cyst, a ventricular aneurysm, and an extracardiac lesion. Solid tumors of the

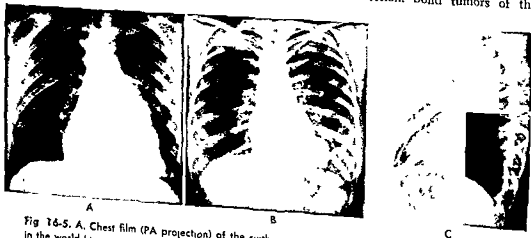

Fig 16-5. A. Chest film (PA projection) of the sixth primary hemangioendotheliosarcoma reported in the world literature. Note especially the totally irregular margin of the left border of the heart, deforming the pulmonary salient (i e, pulmonary artery–pulmonary conus–left atrium region) as well as the left ventricular segment (From Glassy and Massey, Amer J. Med. 1950) B. Cyst of the pericardium, grossly deforming the left ventricular segment of the left cardiac border. It simulates, among other lesions, left ventricular aneurysm. The left lateral projection (C) indicates its position in the anterior mediastinum.

heart tend to differ fluoroscopically from aneurysmal lesions in that the former do not pulsate, except synchronously with ventricular systole, and certainly *there is no expansile pulsation.* Differentiation of cardiac tumors from pericardial cysts or from intimately contiguous extracardiac solid lesions usually cannot be accomplished through fluoroscopy.

Infiltrative neoplasms of the myocardium may be inferred by observing a ragged cardiac contour, especially if it is left-sided, i.e., on the pulmonary salient or on the left ventricular segment. Intracavitary primary tumors of the heart, or metastases to the myocardium, are not discernible by fluoroscopic visualization.

Pneumopericardiography. Intrapericardial injection of air has been shown to be, at least theoretically and on several occasions, a practical method for demonstrating tumefaction of the cardiac surface.

Radiologic Opacification Techniques. Lehman et al point out that "selective" angiocardiography, employing the direct placement of the dye into the outflow tract of the right ventricle, probably would be the procedure of choice in order to demonstrate an intraatrial myxoma, for example One could expect a satisfactory demonstration of such a tumor in a person with that provisional diagnosis.

Failing in that procedure, and provided the patient has a good-sized left atrium, the most preferable alternative procedure would be that of direct (needle) opacification of that chamber, to attempt demonstration of the existence of an intraatrial mass.

Ventriculography by the technique of Lehman et al could demonstrate left intraatrial tumors only if there is severe mitral insufficiency, because otherwise the dye is propelled forwards instead of backwards. To date, intraventricular tumors have not been demonstrated by this method of direct ventriculography.

PRIMARY TUMORS OF THE MYOCARDIUM

Varieties. There are many varieties of primary myocardial tumor. The commonest are described below

RHABDOMYOMAS. *Rhabdomyomas* are primary myocardial, usually ventricular, tumors comprised of striated muscle fibers and also known as *myoma striocellulare.*

Rhabdomyomas are found most often in infancy. Because of their frequent association with (von Gierke's) *glycogen-storage* disease, much interest has centered around determination of their origin. *Tuberous sclerosis* is also found in half of the patients with rhabdomyomas. This interesting disease helps to uncover cardiac rhabdomyomas more readily because of the more apparent neurologic symptoms and signs Multiple renal tumors and adenoma sebaceum tend to be associated with the rhabdomyomas. Since there is some tendency for them to localize as nodules near the apex, it may be possible to identify an irregular left ventricular margin on the roentgenogram and thus to make a provisional diagnosis. The tumors tend to blend histopathologically into adjacent normal myocardium.

Because of its obscure pathogenesis, perhaps the term *rhabdomyoblastoma,* indicating the existence of a tumor whose cells tend to differentiate into striated muscle cells, would be more applicable.

RHABDOMYOMYXOMA. *Rhabdomyomyxoma* is the term used to indicate a tumor comprised of both myxomatous and rhabdomyomatous tissue All these tumors are benign and theoretically potentially amenable to surgical intervention.

MYXOMAS. *Myxomas* are the most common primary neoplasms of the heart. Some physicians regard them as deriving from an organized thrombus and are reluctant to attribute a neoplastic character to them. Others feel they are, indeed, true tumors arising from embryonal mucoid tissue-rests. Their gross consistency is soft and gelatinous, resembling the mucinous connective tissue normally found in the umbilical cord

Predominantly left-sided (of the heart) in origin, the myxoma is typically a lesion of the left atrium, but has been found to originate at the base of the left atrium, *in the left* ventricle, or occasionally in any of the other chambers of the human heart. Controversial tumors of the heart valves have been identified upon occasion as myxomas.

LEIOMYOMA. Leiomyomas of the heart are benign tumors constituted of unstriped muscle fibers Anaplastic instances may be referred to as *leiomyoblastomas.*

FIBROMA. Fibromas are benign, solid tumors of myocardium which are composed exclusively of mature connective or fibrous tissue. In the cardiac wall, these do not undergo the cystic degeneration often displayed by uterine fibromas.

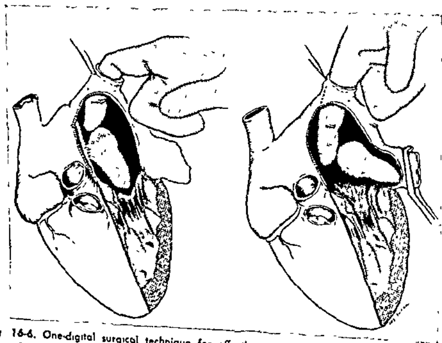
MESOTHELIOMA Mesothelial tissue, derived from the mesoderm to produce pericardium, pleura, and peritoneum, provides the cells which comprise the tumor known as mesothelioma Flat cells of mesodermal origin lining the coelom, or body cavity of the embryo, are the basis for the term coelothelioma, synonymous with mesothelioma Mesotheliomas most often develop in the area of the AV node Their location at the base of the interatrial septum, around the node, and at the beginning of the bundle of His, makes them apt to cause either incomplete or complete heart block

OTHER TUMORS. *Lipomas, xanthomas, teratomas*, and other less common primary benign tumors may occur in the myocardium Practically, i e, therapeutically, these have the same importance as the other neoplasms described above, with the exception of the debatable myxoma

Benign tumors involving the basic elements of the lymphangioendothelial system are seen infrequently, *angiomas, hemangiomas, lymphangioendotheliomas,* and *angioreticulomas.*

LEUKEMIC INFILTRATION OF THE HEART. Infiltration of the myocardium is not an uncommon circumstance in cases of leukemia, although essentially no work has been done to correlate the clinical and electrocardiographic manifestations with those of the necropsy examination. The leukemic cells which may be lymphogenous or myelogenous are found in both the capillaries and in the myocardial interstitial tissue Several cases in the literature have disclosed cardiac involvement sufficient to produce incomplete heart block; only one instance of complete AV dissociation has been described.

While both clinical and electrocardiographic evidence of cardiac abnormality may exist in leukemic individuals, these usually (and perhaps logically) are attributed more readily to rheumatic, arteriosclerotic, or other potential causative factors The electrocardiographic patterns depend upon the individual peculiarities of the leukemic infiltration and obviously exclude the existence of a pathognomonic tracing



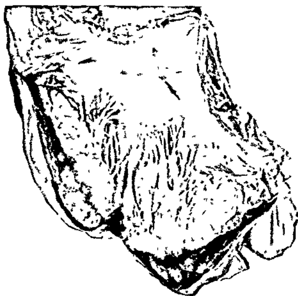


Fig 16-6. One-digital surgical technique for effecting removal of pedicled intraatrial tumor. (From Bailey et al, Surg Clin No Amer., 1951)

Treatment. PRIMARY BENIGN TUMORS. Since surgical techniques have progressed to the degree of perfection they display today, it is desirable to diagnose a tumor of the heart as promptly and as precisely as possible This may allow suitable surgical survey and possible curative excision of several of the most common tumors, both intracavitary and intramural. Successful removal of a 3½-lb primary lipoma of the myocardium was reported by Maurer (1952). Beck had done a similar, pioneering excision (1942). (Fig. 16-6.)

PRIMARY MALIGNANT TUMORS While it is conceivable that effective surgical excision of a circumscribed, delimited malignancy of the myocardium may be achieved, this remains to be demonstrated convincingly. Nichols et al have shown that recurrent, slow-growing tumors of the heart may be managed in just such a fashion, as long as their site is not critical.

A

B

Fig. 16-7. A Margaric nodules, secondary to malignancy of the urinary tract, appearing in the ventricular myocardium. B. Two tumor vegetations on a mitral valve The one in the center is near the free border of the cusp, while the one on the right is at the base of the cusp These neoplastic endocardial implants were metastatic from a bronchogenic carcinoma, and their appearance on the mitral valve seems to be the first reported instance of secondary lesions involving that structure (From Coller et al., Am. J. Clin. Path., 1950)

SECONDARY TUMORS OF THE MYOCARDIUM

Varieties. Metastatic carcinoma invades the myocardium with appreciable frequency, developing as discrete *nodules epicardially* and *intramurally*, and causing *miliary infarcts* and *coronary arterial emboli*. It may occasionally develop in the form of *carcinomatous lymphangitis* As stated previously, these lesions may develop in any area of the heart, although there is little tendency for the endocardium to be involved. Recently, very striking photographic examples of intravalvular metastases have been displayed, even though the incidence there is very low. Right-sided metastatic cardiac lesions predominate (Fig. 16-7A and B)

Infiltrative lesions make their appearance via lymphatic routes or by direct myofibrillar invasion *Hematogenous spread* tends to follow ulceration or rupture into a venous channel, such as a pulmonary vein or the inferior vena cava. Each particular case is individualized in this respect.

Hodgkin's disease, malignant lymphoma, leukemia, myeloma, lymphosarcoma, and reticulum-cell sarcoma comprise the vast majority of the infiltrative processes Unique instances of other systemic diseases producing myocardial infiltration have been reported

In the author's review of histopathologic material (from King County Hospital, Seattle, School of Medicine), the following were among the secondary tumors of the heart:

Case	*Primary*	*Secondary*
F L	Carcinoma, bronchial cleft	Myocardium
A T	Carcinoma, rectum	Epicardium
W. S F	Squamous cell carcinoma, lung	Myocardium
E G	Sarcoma of foot, type not noted	Myocardium
J. E H	Epidermoid carcinoma, buccal mucosa	Myocardium
G L	Malignant melanoma	Myocardium
M J B	Carcinoma, adrenals	Myocardium
L. L.	Adenocarcinoma, thyroid	Right atrium
D McD	Squamous cell epithelioma	Myocardium

Treatment. Since the secondary lesions represent only a phase of widespread disease, the proper treatment obviously remains that of the basic process

Other than symptomatic relief of pericardial effusion with or without cardiac tamponade because of associated pericardial extension, there is nothing specific to offer in the way of effective therapeutic measures directed against the myocardial malignancy Urethane, nitrogen mustard, triethylene melamine, radioactive phosphorus (P^{32}), or radioactive gold (Au^{198}) have been employed with unpredictable and equivocal results

TUMORS OF THE PERICARDIUM

Benign. Fibromas, lipomas, and angiomas may involve the pericardium, thickening or bulging it, but usually without producing clinical symptoms If diffuse, any of these lesions might cause constrictive symptoms Ordinarily, the pericardial space is preserved in their presence

Teratomatous cysts, derived from the region of the third branchial arch, characteristically are attached to the anterior (ventral) aspect of the pericardium, apparently having been drawn down into the thorax during the embryonic descent of the heart In at least two instances, they have been found within, and removed from, the pericardial cavity (Neugebauer, Beck) Most such teratomas fortunately are benign

TREATMENT Surgical removal of a benign tumor of the pericardium has never presented unusual difficulty. The technique consists of merely removing the involved portion of the pericardium with a sufficiently wide margin to ensure a complete excision.

Malignant. These lesions tend to be separated clinically into (1) those which remain in, and extend within, the pericardial substance alone, and (2) those which tend to invade the heart Mesotheliomas are likely to follow the former pattern of behavior while sarcomas usually extend directly into the contiguous myocardium, producing a "lumpy" cardiac border on the teleoroentgenogram (Fig 16-5A)

With the former type of lesion, voluminous pericardial effusion is common, being serous at first, then hemorrhagic It produces symptoms and signs of cardiac compression, recurs rapidly after paracentesis, and frequently contains tumor cells Cytopathologic examination of sedimented debris from the aspirated fluid often reveals the nature of the process.

When the heart is invaded directly, obstruction of either vena cava is common, while symptoms of cardiac constriction may occur due to the woody encasement of the ventricles. Signs of congestive heart failure may develop because of extensive malignant cellular invasion and eventual total replacement of the normal muscle fibers. The successful surgical treatment of such lesions has not yet been reported

CYSTS OF THE PERICARDIUM

Incidence. Pericardial cysts are rare, although not as unusual as the sparse reports of 103 cases up to 1957 would suggest. Lenkert was the first to report such a lesion (1928). With the mass roentgenographic surveys now being made, pericardial cysts should be recognized with increasing frequency.

Classification. Cysts of the pericardium may be designated as acquired or congenital Acquired cysts usually amount to pericardial enclosures of a pocket of exudate Congenital pericardial cysts often are referred to in other terms, e g, as pericardial diverticuli, pleuro-

pericardial cysts, pleurocoelomic cysts, pericardial coelomic cysts, or pericardiophrenic angle cysts.

True pericardial cysts are semitransparent, thin-walled sacs attached to the pericardium; they may contain up to a liter of serous, watery transudate. Apparently, they are composed of tissue resembling pleura and pericardium. Drash and Hyer propose that they be known as mesothelial mediastinal cysts. The walls contain collagenous connective tissue lined by a single layer of cells, characteristically flattened, but which may assume a cuboidal "epithelial" appearance.

Pathogenesis. These cysts generally are believed to be of congenital origin whether one accepts Lambert's theory of failure of complete coalescence of the several mesenchymal lacunae into the primitive pericardial coelom, or Lillie's presumption of "pinching-off" of diverticulum-like structures (such as the ventral parietal recess) which normally appear in the development of the pericardium.

Clinical Importance. Of themselves, pericardial cysts are of minor clinical importance, but often they involve neat, if difficult, differential diagnosis. Lesions from which these intrathoracic cysts must be differentiated include (1) extrapericardial fat pads, (2) esophageal hiatus hernia, (3) partial diaphragmatic eventration, (4) cardiac aneurysm, (5) cardiac tumor, (6) teratoma, (70) lipoma, (8) lymphangioma, (9) secondary hydatid cysts, and (10) subphrenic abscess.

Symptoms. Clinically, these cysts are always benign and regularly produce no symptoms except (occasionally) vague thoracic pain Undoubtedly, there is always possibility of such enlargement as to encroach upon the respiratory reserve and cause shortness of breath and coughing.

In more than one-half of the cases, they appear in one of the cardiophrenic angles, usually the right, and if large, may lose their rounded outline and become flattened due to the effect of gravity. Some are attached by pedicles and may change position, as well as shape, with alterations in posture: a diagnostic feature. Occasionally they exhibit luminal communication with the pericardial sac. Friedberg then uses the term *pericardial diverticulum* or "pseudocyst."

Diagnostic Methods. Nearly always the presence of the mass is detected incidentally through an x-ray observation (Fig 16-5B and C). Additional means of specifically diagnosing the presence of a pericardial cyst include (1) further roentgenographic studies including oblique views and laminograms as indicated, (2) angiocardiography; (3) pneumoperitoneum; (4) observation of the patient over a period of months; (5) Funch's method of aspiration and injection of air; and (6) thoracotomy (the only certain method of diagnosis).

Differential diagnosis between two easily confused mesodermal lesions is presented below, based upon findings evident at thoracotomy.

Pericardial cyst	*Lymphangioma*
Simple structure, i e, unilocular	Complicated structure, i e, multilocular
Walls, thin (mesothelial)	Thicker walls, contiguous adherence
Blood supply from pericardium	Blood supply from pericardium and elsewhere

MYOCARDIAL ALTERATIONS CAUSED BY PHYSICAL OR CHEMICAL AGENTS

PHYSICAL INJURIES TO THE HEART

Traumatic Injury. Moritz (1942), in his discussion of the mechanisms of injury by physical violence has made clear the distinction between *primary* (or *direct*) and *secondary* (or *indirect*) myocardial injury *Primary injury*, functional, structural or both, was defined as that resulting from a force directly applied or transmitted to the heart The designation *secondary injury* was given to cardiac disturbance resulting from disruptive or functional changes produced elsewhere in the body by a traumatizing agent

PRIMARY TRAUMATIC INJURY. The force responsible for a direct injury can be a *penetrating* wound (such as that resulting from a flying missile, or a slender, rigid object) or a blunt impact Since a missile travels at much higher velocity, it ordinarily causes much more extensive injury than a stab wound The latter tends to close when the force is withdrawn and this explains why the victim may survive long enough to undergo surgical repair of the defect It has been indicated that the clotted blood filling the intramyocardial wound is slow to resorb and that fibroblastic proliferation is seldom well under way before 2 weeks have elapsed, however, Moritz (1953) has seen epicardial and endocardial fibrous plaques at the sites of entrance and exit of a penetrating wound, a month after its infliction, in the absence of any other detectable alteration.

The most important complications of a penetrating myocardial wound are shock, hemorrhage, and infection If the associated *pericardial* defect is large enough, the escaping blood tends to collect in the pleural cavities, if blood does not escape from the pericardial cavity rapidly, it collects in the pericardial space and the consequent rise in intrapericardial pressure will lead to cardiac tamponade.

Commotion, contusion, and *laceration*, according to the strength of the disruptive force, are the main effects of a blunt precordial impact. *Cardiac commotion*, by definition, indicates a disturbance in function not accompanied by structural alteration There are records of the death of human subjects subsequent to blunt injury of the chest, in these cases, death was found to be due to heart failure, despite the absence of structural damage Transient disturbances in cardiac function following impact on the chest have been also reported by several investigators, both in man and *in experimental* animals Schlomka and Schmitz, from animal experimentation, concluded that the cardiac disturbance caused by commotion is secondary to reflex coronary vasoconstriction and myocardial ischemia This concept is well substantiated by the demonstration of dissem-

inated ischemic necrosis in traumatized human hearts and by the finding of foci of myocardial necrosis in animals subjected to nondisruptive cardiac impact (Kastert). The observation that rabbits with cholesterolosis of the coronary arteries are less tolerant to blunt injury of the chest might be correlated to the observation that even a minor precordial trauma can precipitate cardiac failure and death in individuals with lesions of the coronary vascular bed.

The term *myocardial contusion* applies to the condition characterized by escape of blood between the myofibrils (without any other appreciable structural alteration) which results from a blunt force directly applied or transmitted to the heart. Rise of intracapillary pressure and stretching or distortion of the walls of blood vessels are the main causes of the hemorrhage

Aside from penetrating injury, a fall from a height is the most common cause of *laceration* of the heart. The sudden distortion and compression of the organ produces a rise of pressure in the cardiac cavities and causes the myocardium to burst at the point of greatest strain and least resistance, in general the right atrium or ventricle. The defect in the continuity of the tissue may be so small as to be barely detectable with the naked eye or so extensive as to result in rupture of the heart. Moritz and Atkins have produced evidence indicating that the hydrostatic force incident to the sudden compression of the heart by the bony structures of the thoracic cage is the main factor which operates in disrupting the myocardium.

Since in the first four or five decades of life the thoracic cage is usually sufficiently plastic to permit distortion without fracture, cardiac commotion, contusion, and laceration are more likely to occur in the absence of disruptive bony injury On the other hand, a rigid, more easily fractured, thoracic cage is an important factor in protecting the heart from a blunt force

Myocardial contusions and lacerations may occur during rhythmic manual compression (of the heart) of the type which is employed for resuscitation of the heart Tedeschi and White have shown that the fibrillating heart is more likely to be injured than the normally beating heart because it is relatively rigid

SECONDARY TRAUMATIC INJURY. The normal myocardium is not permanently affected by stresses following a disruptive trauma elsewhere in the body. However, the same injury may represent a potential threat to a heart already handicapped by an organic disorder The frequency with which a fatal attack of acute myocardial hypoxia is initiated during exertion points out the danger of a pressor episode in an organically diseased heart and even in a heart which is in a borderline condition compatible with an apparent state of health.

As a result of a mechanical disruption of tissues, several types of emboli may penetrate the circulatory system and reach the chambers of the heart. Blood stasis, tissue edema, and muscular inactivity are frequent sequelae of traumatic injury and these conditions predispose to venous thrombosis and embolism Emboli of hepatic cells within the cardiac chambers may be seen in disruptive injury of the liver. Entrance of air into the circulating blood through patent veins, and of fat droplets from disrupted skeletal or extraskeletal fat, are other possible sources of embolism. Fatal occlusion of the anterior descending branch of the left coronary artery by a small amount of fat was seen by the author. In this case the patient was the victim of a tornado and died suddenly 24 hr after an apparently mild injury to extraskeletal adipose tissues. There was associated pulmonary embolism which had given only a minimal degree of functional disturbance, namely, a mild degree of dyspnea during the interval between injury and death

Injury Caused by Changes in Atmospheric Pressure. Whenever the human organism undergoes a sudden, marked reduction in atmospheric pressure, the change in tension releases some of the gases from solution, and air bubbles, mostly inert nitrogen and carbon dioxide, enter the blood stream giving rise to one form of air embolism In fatal cases, large air bubbles can be found in the right heart soon after death, although other cardiac alterations will be absent.

Blast Injury. Blast injury is the disruptive effect in the tissues resulting from a sudden change in pressure brought about by the force of an explosion. The force may be transmitted through either air (air blast), water (immer-

sion blast), or rigid structures (solid blast) The walls of the hollow viscera, including the heart, are particularly susceptible to this type of injury, which is often seen when there is little or no external evidence of trauma.

Hypothermal and Hyperthermal Injury. HYPOTHERMAL. Circulation fails when the temperature of the blood is reduced to the vicinity of 20°C. In individual cases, port-mortem examinations have disclosed right heart dilatation and pulmonary edema Hoff and Nahum have described the use of metal thermodes for the investigation of the local effects of hypothermal injury Taylor et al. have produced transmural muscle necrosis by using an instrument cooled to −60°C with expanding carbon dioxide.

HYPERTHERMAL Those systemic disturbances caused by cutaneous burns may result in a variety of secondary disorders mostly due to hemoconcentration, low blood pressure, and the systemic hypoxia of secondary shock. Although the effects of the impact of the generalized disturbance are most apparent in the kidneys, liver, and adrenals, degenerative changes in cardiac myofibrils and endocardial mural thrombosis have been observed in fatal cases

In systemic hyperthermia, a general rise in the temperature of the circulating blood above 42.5°C results in generalized vasodilatation, reduction in effective blood volume, and changes in respiration: first stimulation and then cessation Cardiac dilatation and the structural deterioration of the myofibrils explain the impairment of cardiac efficiency and the rapid pulse which occur under these conditions

Electrical Injury. The path of a current through the body tends to follow the most direct route between the sites of entrance and exit The principal conductors of the electric current are the fluids, and most of the current travels along the vessels In flowing through the tissues, the current may (1) produce destruction of cells by heat or electrolysis, (2) stimulate strong muscular contraction, or (3) inhibit the function of vital centers that lie in its path The nature and degree of harmful effects are dependent upon a combination of conditions, mainly the duration of the current, its path, and its amperage and voltage. The mechanism of death from electricity is still a matter of much dispute Some consider that it is due to cardiac paralysis, others to paralysis of the respiratory centers When a low-tension current passes through the heart, fibrillation occurs On exposure to high-tension current, the function of the heart stops abruptly. Pathognomonic alterations take place in neither case. Petechial hemorrhage in the pericardial membranes results from the vascular damage of acute systemic hypoxia.

The effect of alternating current, countershock, and condenser-discharge countershock on the fibrillating canine heart have been investigated by Tedeschi and White. Both epicardial and myocardial damage was found at the site of application of the electrodes. The damage was manifested initially by epicardial fibrinous hemorrhagic exudation, necrosis of subepicardial fat, fragmentation and necrosis of the myofibrils, and inflammatory reaction. Pericardial adhesions and superficial myocardial fibrosis were observed subsequently in the animals that survived Alternating current was productive of more severe changes than condenser-discharge current and the injury was not influenced by the type of electrode surface using either type of current.

Radiation Injury. The median lethal dose for different cells and organisms varies widely, and a wide range of radiosensitivity exists among cells of a single type. Nevertheless there are average differences in cell resistance and sensitivity to radiation of a magnitude large enough to be of practical significance With respect to vulnerability to radiation, a classification has been proposed by Warren, according to which the tissues are divided into three main categories: (1) To the *radiosensitive* category he allocates those tissues which become seriously injured on exposure to 2,500 r or less (2) The *radioresponsive* category comprises those tissues which suffer serious injury on exposures ranging from 2,500 to 5,000 r. (3) The *radioresistant* tissues are those which become damaged on exposures to more than 5,000 r. The myocardium belongs in the last category The only significant cardiac changes observed by Liebow et al among victims of the Hiroshima and Nagasaki atomic bomb explosions were subendocardial and epicardial petechial hemorrhages, occasional infiltration

inated ischemic necrosis in traumatized human hearts and by the finding of *foci of myocardial* necrosis in animals subjected to *nondisruptive* cardiac impact (Kastert). The observation that rabbits with cholesterolosis of the coronary arteries are less tolerant to blunt *injury of the* chest might be correlated to the observation that even a minor precordial trauma can pre*cipitate cardiac failure* and death *in individuals with lesions* of the coronary vascular bed.

The term myocardial contusion applies to the condition characterized by *escape of blood* between the myofibrils (without any other appreciable structural alteration) which results from a blunt force directly applied or transmitted to the heart. Rise of intracapillary pressure and stretching or distortion of the walls *of blood vessels* are the main causes of the hemorrhage.

Aside from penetrating injury, a fall from a height is the most common cause of *laceration* of the heart The sudden distortion and compression of the organ produces a rise of pressure in the cardiac cavities and causes the *myocardium* to burst at the point of greatest strain and least resistance, in general the right atrium or ventricle. The defect in the continuity of the tissue may be so small as to be barely detectable with the naked eye or so extensive as to result in rupture of the heart *Moritz and Atkins* have produced evidence indicating that the hydrostatic force incident to the sudden compression of the heart by the bony structures of the thoracic cage is the main factor which operates in disrupting the myocardium.

Since in the first four or five decades of life the thoracic cage *is* usually sufficiently plastic to permit distortion without fracture, cardiac commotion, contusion, and laceration are more likely to occur in the absence of disruptive bony *injury*. On the other hand, a rigid, more easily fractured, thoracic cage is an important factor in protecting *the heart* from a blunt force.

Myocardial contusions and lacerations may occur during rhythmic manual compression (of the heart) of the type which is employed for resuscitation of the heart. Tedeschi *and White* have shown that the fibrillating heart is more likely to be injured than the normally beating heart because it is relatively rigid

SECONDARY TRAUMATIC INJURY. The normal myocardium is not permanently affected by *stresses following* a disruptive trauma else*where in the body*. However, the same injury *may represent a potential threat* to a heart *already handicapped* by an organic disorder The frequency with which a fatal attack of acute myocardial hypoxia is initiated during exertion points out the danger of a pressor episode in an organically diseased heart and even in a heart which is in a borderline con*dition* compatible with an apparent state of health.

As a result of a mechanical disruption of tissues, several types of emboli may penetrate the circulatory system and reach the chambers of the heart. Blood stasis, tissue edema, and muscular inactivity are frequent sequelae of traumatic injury and these conditions predispose to venous thrombosis and embolism Emboli of hepatic cells within the cardiac chambers may be seen in disruptive injury of the liver. Entrance of air into the circulating blood through patent veins, and of fat droplets from disrupted skeletal or extraskeletal fat, are other possible *sources of embolism*. Fatal occlusion of the anterior descending branch of the left coronary artery by a small amount of fat was seen by the author. In this case the patient was the victim of a tornado and died suddenly 24 hr after an apparently mild injury to extra*skeletal adipose tissues There* was associated pulmonary embolism which had given only a minimal degree of functional disturbance, namely, a mild degree of dyspnea during the interval between injury and death

Injury Caused by Changes in Atmospheric Pressure. Whenever the human organism undergoes a sudden, marked reduction in atmospheric pressure, the change in tension releases some of the gases from solution, and air bubbles, mostly inert nitrogen and carbon dioxide, enter the blood stream giving rise to one form of air embolism. In fatal cases, large air bubbles can be found in the right heart soon after death, although other cardiac alterations will be absent

Blast Injury. Blast injury is the disruptive effect in the tissues resulting from a sudden change in pressure brought about by the force of an explosion. The force may be transmitted through either air (air blast), water (immer-

lomas. However, Fawcett, in a critical attempt to reassess the problem, studied the incidence of this picture as it occurred one year prior to and one year following the advent of sulfonamide chemotherapy and found an almost identical number of cases in the two groups. Further caution in approaching the subject is suggested by the failure of Merkel and Crawford to demonstrate myocardial changes in five patients whose death had been attributed to sulfonamide hypersensitivity The author has had two comparable experiences.

CLINICAL ASPECTS OF TRAUMATIC HEART DISEASE

NONPENETRATING INJURIES

Borch (1676) published the first probable case history of nonpenetrating cardiac trauma. An 8-year-old boy had fallen between a table and a footstool, bruising his chest He died 4 months later, and the necropsy revealed a large right atrium which was described as "pale, yellow, and nearly decayed" These pathological findings were considered to be the result of trauma However, this explanation of their origin is open to doubt

Akenside (1764) reported what is probably the first unquestionable case A 14-year-old boy complained of chest pain and developed a cough with hemoptysis immediately after being struck between two ribs by the edge of a plate. He lived about 6 months thereafter. Following his death, the necropsy revealed an area of necrosis the size of a half-crown on the left side of the heart, and a totally adherent pericardium

Historical Considerations and Incidence. Warburg reviewed the literature and found that, from 1676 to 1868, only 27 cases of cardiac trauma were reported The impressive work of Fischer was published at that time and, while he collected 76 case histories, only seven described myocardial contusions and none traumatic cardiac rupture The number of cases reported has greatly increased since 1900, but still many clinicians and pathologists consider the condition rare. Fifty unselected consecutive victims of fatal automobile accidents were examined by Leinoff, and he found that eight (16 per cent), showed microscopic evidence of cardiac damage In a review of 1,000 necropsies of contusion of the chest, Urbach found that 185 (18.5 per cent) showed injury to the heart.

Method and Mechanism of Injury. Urbach lists these mechanisms of injury in their order of frequency.

1. Falls from a high place
2. Blows from the fist
3. Kicks
4. Blows by heavy objects or wagon tongues
5. Butting by animals

These causes, however, do not apply to a machine age, and during the past 40 years most blows to the chest have been caused by striking the steering wheel or instrument panel of an automobile, or the back of an automobile seat Blows received on the anterior or left side of the chest most frequently produce cardiac injury. The force of these blows need not be sufficient to fracture the bony cage or cause more than minor contusion to the chest wall The heart may also be injured by compression of the chest from various angles, most frequently from front to back.

Pericardial and Epicardial Injury. The factors that predispose the pericardium to injury are anatomical, such as attachment to the central tendon of the diaphragm, fixation by the sternopericardial ligament to the inner side of the sternum, frequent fusion with the pleura, irregularity of thickness, amount of fat, and elasticity Blows that varied in intensity from that of a hard rubber mallet to a 10-lb sledge hammer were struck on the chests of 19 anesthetized dogs, and the most frequent injuries to the pericardium were pericardial and epicardial hemorrhages and tears These lesions, when uncomplicated by myocardial contusion, are usually due to relatively moderate blows In 26 human cases that came to necropsy as the result of severe extracardiac injury with only mild to moderate chest trauma, *subpericardial hemorrhage* occurred in all but two cases, *pericardial hemorrhage* in ten, and small pericardial or epicardial tears in four. All these patients died within 2 weeks subsequent to injury and, in the remaining twelve who survived from 6 to 18 months, subpericardial fibrosis occurred nine times These subpericardial hemorrhages are usually anterior and near

by inflammatory cells, fatty change in one instance, and focal myocardial necrosis in another. Thibaudeau and Mattick autopsied patients dying from 2 days to 1 year after radiation treatment that included exposure to the heart. They noticed changes in the myofibrils ranging from granular or vacuolar degeneration to hyaline change and necrosis with occasional slight interstitial fibrosis and sometimes round-cell infiltration. Although radiation injury of the myocardium, as elsewhere in the body, has no specific features, the combination of aseptic necrosis, fibrosis, and obliterative endoarteritis is considered sufficiently characteristic to warrant identification (Warren).

CHEMICAL INJURIES TO THE HEART

Poisons may injure by local action at the point of entry, by their action upon distant organs following absorption, or by a combination of both mechanisms. Local myocardial injury by chemical agents is prevented in the human being by the particular situation of the organ. In experiments on the exposed heart, local application of phenol has resulted in death within 1 hr, probably due to the systemic effects of the substance. Myocardial necrosis was produced by means of local application of sponges saturated with formalin, or by intramyocardial injections of solutions of mercuric chloride (5 per cent) and silver nitrate (20 per cent).

Among the poisons with systemic effects, similar myocardial lesions are produced by a wide range of substances, and perhaps the common underlying factor is interruption of the oxygen cycle either outside or within the cardiac tissue.

In anesthetic death and in death caused by hypnotics and sedatives of the barbiturate group, hypoxia is brought about by depression of the respiratory centers

Interference with normal respiratory function, secondary to pulmonary edema and hemorrhage, is the mechanism operating in the hypoxic state that results from exposure to phosgene, chlorine, sulfur dioxide, and other irritant gases.

Hemolysis, as it occurs in arsine intoxication, also results in a condition of anoxemia, and a similar mechanism operates in the anoxemic death that ensues after exposure to bone-marrow depressants, such as benzol.

Inactivation of the respiratory enzymes of cardiac tissue follows poisoning by cyanide compounds.

Oxygen deficiency is a major aspect of carbon monoxide poisoning and myocardial necrosis may be one result. Ehrich et al. exposed dogs to a concentration of carbon monoxide greater than 75 per cent for 15 min to 1 hr and found myocardial necrosis, hemorrhage, and early deposition of calcium salts Comparable myocardial alterations, particularly in the papillary muscles, were observed in human beings dying of carbon monoxide poisoning. Inflammatory changes, interpreted as secondary to the muscle necrosis, were also noted The sudden occurrence of coronary thrombosis and of myocardial ischemic necrosis weeks or months after recovery from the poisoning has been observed.

As an example of the type of injury caused by the mineral poisons, the extensive fatty degeneration of the myofibrils occurring in fatal cases of acute phosphorus intoxication is well known.

Cor pulmonale and right heart failure are prominent features of *berylliosis* Pulmonary granulomatosis and fibrosis, and obliterating endarteritis are largely responsible for the cardiac changes in this condition.

Alkaloids and glucosides comprise a number of complex organic compounds, many of which are used therapeutically. In excessive doses they may induce toxic effects, which are revealed by diversified physiologic disturbances and structural alterations. Early focal myocardial necrosis, inflammatory-cell infiltration, and late connective-tissue proliferation, were shown by La Due and by Dearing et al. in animals given large doses of digitalis.

The possibility that *drug hypersensitivity* may result in myocardial changes has been suggested by several investigators, but work in this area has developed particularly since the advent of sulfonamides Considerable evidence has been gathered in favor of the contention that myocardial damage may result from the administration of sulfonamides to sensitive individuals Simon has succinctly summarized the pathological characteristics of the lesion which consist mainly of necrotizing arteritis, necrosis of the myofibrils, and exudative reaction (including eosinophilia), which may progress to the formation of mature granu-

a result of accidents such as falls from a height or burial under an avalanche of debris. It is postulated that this type of accident greatly increases the diastolic pressure of the aortic column of blood against the closed aortic valve This concept is supported by the fact that usually the *tears* are only partial, because, as soon as the rupture occurs, the pressure is relieved The passing of a stiff catheter through the valve against the flow of blood will rupture or injure the cusp in a high percentage of instances.

The anatomy of the mitral valve is different with its large, broad, thick cusps supported by the chordae tendineae that act as a protection from rupture. It is postulated that overextension of the cusps during compression of the heart results in rupture of the chordae tendineae and papillary muscles rather than of the valve leaflets Small incomplete tears and areas of hemorrhage may occur on the atrial side The latter type of lesion is also found on the pulmonic and tricuspid valves, but rupture is rare and, when it occurs, it is invariably associated with other severe cardiac injuries The question of *infectious endocarditis* following cardiac trauma is controversial and, in the majority of the cases reported, the lapse of time was inconsistent with cause and effect

Rosenbach, Orth, Wyssokowitsch, and Weichselbaum were the first to experimentally produce traumatic valvular endocarditis by injecting bacteria into the circulation following injury to a valve It is possible, as suggested by Litten and others, that the thrombus formation at the site of small endocardial injuries may become a focus for a subsequent infectious endocardial process and the accumulation of thrombotic vegetations. It is unlikely that an uncomplicated injury to a valve will, in the healing process, create sufficient thickening to produce a stenosis However, if complicated by infection (especially one of rheumatic origin), the thickening, contraction, and adhesions of the cusp can produce stenosis. There is a question as to just how bacteria enter the heart following nonpenetrating injuries while other organs, such as the spleen, when contused or even ruptured, rarely develop infection Frequently, there is some other injury to the body which could provide a point of entry Subacute bacterial endocarditis can be superimposed upon a traumatic lesion.

Cardiac Rupture. Rupture due to bursting may produce a sharp, smooth, clean-cut wound, larger on the outside of the myocardium than on the inside, and usually it does not approximate the place where the force was applied As a rule, these lesions are lengthwise in the ventricles Rupture can occur within a few days after myocardial contusion, when the area is undergoing necrosis, or still later, when the healing process has produced thinning of the myocardial wall and subsequently a cardiac aneurysm. Ruptures frequently occur at the base or margin of the atria, base of the tricuspid valve, and at the junction of the large vessels, especially the veins, due to violent displacement of the heart. Occasionally, the heart is torn completely loose, and has been found free in the pleural cavity

Injury to the Great Vessels. Injury to the great vessels is frequently caused by violent displacement of the heart in the chest, and usually is a complication of cardiac trauma. Crynes and Hunter found that lacerations of the inferior vena cava were frequently accompanied by fractures of the lower ribs on the right side, and Stephens (1922) reported a case with a fracture of the sternum, and a tear of the superior vena cava These injuries are not as frequent as those that affect the aorta. Ruptures and tears with aneurysmic formation due to displacement most frequently occur at the top of the arch of the aorta This can be explained on an anatomical basis, as postulated by Jaffe and Sternberg (1919) and by Shennan (1929). The ligamentum arteriosum joins the aorta near the root of the left lung and is anchored to the vertebral column by connective tissue The aortic attachment acts as a fixed point, and the resulting hinge-like action is responsible for the localized point of injury. The tears are transverse. Also, the anterior wall of the aorta is not as thick as the posterior, and the latter may be crushed against the vertebral column as the result of a blunt impact as well as of direct violence to the chest.

A sudden and violent compression of the systemic arteries, sufficient to markedly distend the aorta at the time of cardiac systole, can cause the intima to rupture and blood to extravasate, gradually distending the elastic coat and occluding the vasa vasorum with resulting

the large arteries, and vary in size from small petechiae to large bruised areas. The infrequency with which uncomplicated hemorrhages of the pericardium are found at necropsy is due to their tendency to absorb completely. Reiss et al. described a case which showed areas of epicardial and pericardial hemorrhage, with clinical evidence of pericardial damage that was probably due to the frequent intermittent use of an *electric pacemaker* for controlling complete heart block with Stokes-Adams syndrome.

In severe injuries caused by being crushed or falling from a high place, the force is transmitted from within, rupturing the myocardium first, and then the visceral pericardium. During violent compression, the great vessels are shut off, putting the fluid mass under great tension which produces rupture through the expanding internal pressure. Tears at the roots of the great vessels appear to be due to violent displacement of the heart. *Infectious pericarditis, pneumopericardium, hemopericardium,* and *herniation of the heart* due to pericardial retraction, are the most frequent complications of pericardial rupture. The small lacerations, hemorrhages, and contusions of the pericardium frequently heal without adhesions. However, when adhesions do occur, they may range from a single fibrous stand to an adhesive pericarditis. Constriction of the superior vena cava, its branches, the trachea, the bronchi, the esophagus, or even fixation of the heart, may result from adhesions caused by hemorrhage (with or without infection) into the posterior-mediastinal space.

Myocardial Injury. The early myocardial lesions of contusion are characterized by hemorrhage into the interspaces between the muscle fibers; these appear to crowd the fibers aside. There is also fragmentation and tearing of the muscle fibers. The smaller hemorrhages are usually found in subepicardial or subendocardial areas. However, these areas may only be the apex of a large triangular area of myocardial contusion. Occasionally, the papillary muscles are involved and sometimes torn. The pathological changes develop in the following manner: first the muscle fibers lose their transverse striations, then become swollen with granular or lumpy protoplasm, and are finally surrounded by a wall of granules and polymorphonuclear leucocytes. This lesion is usually the result of severe contusion, deeply situated in the myocardium and requiring many serial sections to reveal its presence. Grossly, these lesions are more obvious after fixation.

In the older lesions, there is (1) displacement (or replacement) of the myocardial fibers by fibrous-tissue scar formation; (2) muscle-fiber destruction caused by anemic necrosis with absorption, and (3) connective-tissue replacement. These changes frequently lead to aneurysm formation due to myocardial thinning. The lesions are very similar to those of myocardial infarction. Moritz and Atkins reported the similarity. When there is a question of possible or probable trauma, the burden of proof for myocardial infarction rests upon finding a coronary artery occlusion. The older lesions are even more difficult to differentiate because the scars are frequently identical. Hemosiderin and brown atrophy have been observed more frequently in myocardial contusion, but their absence does not exclude trauma.

Endocardial Injuries. These lesions vary from small petechial hemorrhages to large areas of bruising. The larger hemorrhages frequently have the appearance of a hematoma and occasionally the underlying myocardium is necrotic. Frequently, they are *tears in the endocardium* with or without involvement of the myocardium, and they usually heal by scar-tissue formation.

Traumatic rupture of either normal or diseased valves may occur. However, great care should be taken to differentiate the latter from spontaneous rupture. The tears that do not heal result in fragmentation of the free edge of the cusp with occasional severing of the chorda tendinea. Tears or hemorrhage along the base or commissure of the leaflet heal with the formation of scar tissue. The fragmented parts of the valve cusps may grow together, smoothing the rough edges, or become attached to the wall of the heart. Complete healing with obliteration of the opening is rarely accomplished. This process thickens the cusp, thus producing some stenosis with insufficiency. Reubold believes that valvular stenosis and insufficiency can be produced by distortion of the valve ring due to the healing process following hemorrhage or contusion. Most valve ruptures occur on the left side of the heart. The aortic valve is most frequently injured as

with chest pain and at first a slow heart rate but, as *tamponade* develops, the pulse becomes rapid and weak. The heart sounds are muffled and distant as the arterial pressure falls, and the venous pressure is increased with engorgement and distention of the neck veins. As the circulation fails, a marked *pallor with cyanosis* develops, and the patient finally becomes unconscious. Percussion will show an increase in the area of cardiac dullness and the diagnosis can finally be established by tapping the pericardial sac and withdrawing blood One would expect the symptoms and findings of myocardial contusion and those of myocardial infarction with myomalacia to be similar, if not identical, because of the physiological reaction to the pathological process. The differential diagnosis is extremely difficult and occasionally impossible The possibility should be considered that a coincidental coronary-artery occlusion may occur within a relatively short time after an accident However, too many cases of chest injury have been diagnosed as coronary-artery occlusion with complete disregard of a possible myocardial contusion It is also possible that a myocardial contusion can befall a heart that is already damaged by some other type of disease.

Cardiac arrhythmias appear to be influenced by the location of the injury. *Premature contractions* are the most frequent and they originate from any part of the heart. *Atrial fibrillation and flutter, AV or SA block* may occur, and are diagnosed by their characteristic signs, symptoms, and electrocardiographic changes. *Atrial or nodal tachycardia* occasionally occurs, and is not considered a serious complication. However, *ventricular tachycardia, ventricular fibrillation*, and *nodal rhythm*, which occur with cardiac rupture and severe myocardial contusion, can be the cause of *sudden death* within a few minutes after injury Almost every arrhythmia has been produced experimentally These include atrial fibrillation, atrial flutter, premature contractions, *nodal rhythm*, *SA block*, complete AV block, intraventricular block, ventricular tachycardia, ventricular fibrillation, alternating right and left bundle branch block, and various types of nodal rhythm with atrial paralysis.

The electrocardiographic changes are similar, if not identical, to those in coronary occlusion, however, the unipolar leads are useful in locating the position of the injury and identifying traumatic pericarditis. As in myocardial infarction, these changes frequently do not occur until after 24 to 48 hr have elapsed, and therefore serial tracings should be taken This is important because, in myocardial contusion, the electrocardiogram tends to return to normal, or toward the pretraumatic electrocardiogram, in a much shorter time than in myocardial infarction

Cyanosis that cannot be attributed to lung injury is an indication for angiocardiography or cardiac catheterization, since these procedures will identify atrial or ventricular septal ruptures and are helpful in diagnosing acquired left-to-right shunts

If, shortly after an injury, roentgenographic examination of the chest reveals increased density and widening of the upper part of the posterior mediastinal space, examination should be repeated weekly because these changes are evidence of contusion, hemorrhage, and partial rupture of the great vessels. The accepted signs of *aortic aneurysm* may be present from 1 to 4 months. However, pulsation of the shadow is often not seen because of thrombus formation

MANAGEMENT AND TREATMENT

Patients with severe symptoms of cardiac trauma, i.e., dyspnea, orthopnea, or cyanosis should receive oxygen continuously for 4 to 7 days A narcotic or sedative may be necessary to relieve the pain and anxiety. *Pulmonary edema* may develop, especially if there is an associated contusion of the lungs, and this should be treated in the usual manner. However, venesection is not recommended unless it has been definitely proved that the attack is due to heart failure[1] *Digitalis* is indicated when there are signs of congestive heart failure or atrial fibrillation with a rapid ventricular rate, but it will not control the sinus tachycardia which is so frequently present The routine administration of digitalis is not indicated, because the frequent ectopic rhythms suggest that the area of myocardial damage has an increased excitability In the cases of ectopic rhythm established at the time of injury, an immediate attempt should be made

[1] For the mechanism and therapy of pulmonary edema, see Part 18, Chaps 12 to 14 *Editor.*

fusiform or saccular aneurysm formations. *Aneurysms of the aorta* due to peripheral compression (e g., when the patient has been covered by debris and forced into a jackknife position) are usually located in the abdominal portion. External chest injuries that produce bruising, with hemorrhage into the wall of the aorta and tears of the intima, rarely result in a dissecting aneurysm. A traumatic aneurysm is not a true aneurysm but rather a hematoma A saccular aneurysm can form later as a result of the stretching of the scar tissue.

SYMPTOMS, PHYSICAL MANIFESTATIONS, AND DIAGNOSIS

After considering the pathogenesis of traumatic lesions, it is obvious that they will produce similar, if not identical, symptoms and physical findings to lesions produced by other causes. The patient's history is all-important, and a correct appraisal must be made of the cardiac condition before, at the time of, and immediately after, the trauma. With *rupture or tears of the pericardial sac,* there occasionally is a *double, loud and soft, systolic murmur,* with a sharp interruption. This was described by Morel-Lavallée as similar to the sound of water striking the blade of a wheel (water-wheel murmur). The sound may also resemble that produced by blowing into an empty bottle. *Pericardial contusion and hemorrhage* will produce a *soft to rough systolic murmur,* and a *friction rub* may replace the murmur at any time These murmurs may disappear for a few pulsations or upon change of body position.

Severe *precordial pain* developing immediately, or at least within 6 to 12 hr, is the most persistent symptom *Dyspnea* and *orthopnea* occasionally occur, and there may be *precordial distress* on breathing. *Tenderness over the precordium* and *palpitation* are symptoms which persist for some time When the murmur is due to a ruptured valve, it occurs immediately, is constant, and is associated with a characteristic sign of valvular insufficiency Rupture of the chordae tendineae causes a *vibrant murmur,* like the sound of a jew's-harp. It will frequently disappear when the broken chordae become entangled or adhere to the sides of the cardiac cavity.

The cardinal symptom of *myocardial contusion is immediate, excruciating pain* located in the substernal or precordial area and radiating (usually) to the left shoulder and left arm. It may also be referred to both shoulders or to the sides of the neck. The pain is identical with that experienced in coronary insufficiency or coronary occlusion. When the patient is unconscious, or the physician's attention is distracted because of fractures of the ribs or severe injuries to other parts of the body, the substernal pain is not the cardinal symptom and may be overlooked. Occasionally, it occurs after a latent period of from a few days to 2 weeks A *silent myocardial contusion* can occur, as well as a *silent myocardial infarction.* Necropsies have revealed many symptomless myocardial contusions caused by minor injuries. The *serum transaminase* level is elevated as it is in myocardial infarction The symptoms should be differentiated from those produced by contusion and fracture of the thoracic cage. Later, the pain of myocardial contusion can be brought on by exertion, and, like the coronary type of pain, it is referred to the left arm and relieved by rest.

In about 25 per cent of the cases, the appearance of symptoms is delayed up to a month, but the signs of myocardial weakness, revealed by venous congestion and nocturnal dyspnea, usually develop after a short latent period. The most common findings in all cases of myocardial contusion are *tachycardia, palpitation,* and *arrhythmia.* The arrhythmias present their own characteristic signs and symptoms. Frequently, auscultation reveals nothing unusual However, should the heart sounds seem distant at any time, a roentgenogram, electrocardiogram, or even a pericardial tap should be made immediately to confirm the possibility of a *hemopericardium.* In all cases, a roentgenographic examination should be made as soon as possible, not only of the heart, but also of the anterior and posterior mediastinal spaces. The examination will reveal whether or not there has been *hemorrhage about the great vessels.* If it is done early, the films can be compared with subsequent ones, should a question arise in regard to cardiac aneurysm or hemopericardium A roentgen kymogram or electrokymogram offers, not only a means of diagnosis, but considerable assistance in locating the area of contusion in the heart.

Cardiac rupture produces sudden collapse

ture of the left ventricle. Death, however, depends upon the size and the speed of the hemorrhage.

The small pericardial and subpericardial lesions heal uneventfully, but the more extensive or obliterating types may interfere with cardiac output, thus hastening heart failure *Cardiac fixation* due to adhesions frequently results in permanent disability. *Cardiac tamponade* causes sudden death or rapidly progressing failure The heart can also be embarrassed by clot formation in the pericardial sac from even a small wound. Obliteration of the sac by adhesions may result in calcification and an *armored heart* (constrictive pericarditis) A rupture of the pericardial sac which allows blood to escape defeats tamponade and delays death. Pericardial injuries heal more rapidly than those of the endocardium. The prognosis for partial or even complete recovery in cases of uncomplicated mild and moderate cardiac injury is good Uncomplicated hemorrhages have the best prognosis, certainly better than that of contusion or rupture caused by nonpenetrating injuries which involve more than one chamber.

The juvenile heart has a more favorable prognosis because it is smaller, and children are less likely to be exposed to the bursting type of injury. Anderson reduced the possibilities following myocardial contusion to (1) complete recovery, (2) reduced cardiac capacity, (3) pain on effort, (4) congestive failure, or (5) cardiac rupture.

PENETRATING WOUNDS AND FOREIGN BODIES

Historical Background and Mode of Injury. The wound at present is usually produced by a knife, ice pick, bullet, or fragments of bone; earlier causative instruments were spears and arrows. There are many important factors to be considered, e g, (1) the character of the knife blade (was it sharp or dull, blunt-tipped or pointed, round or flat, thin and narrow, or broad and thick); (2) the caliber of the gun and character of the projectile (single or multiple, lead or steel, soft-nosed or hard-jacketed), (3) the distance traveled by the lethal object and the angle at which it entered the body

A penetrating wound of the heart may be caused by a bony fragment, fractured rib, or the sternum, in these wounds there may be no penetration of the thorax It is also possible to have a penetrating wound of the heart due to a foreign body, such as a needle entering from the esophagus or bronchial tree.

Elsberg believed that wounds which were inflicted during systole bled more strongly than those incurred during diastole. He explained that wounds cut during systole become larger in diastolic relaxation, while those cut in diastole become smaller during systole. Harvey mentioned the case of a stag in which a bullet was found lodged within the heart Callender (1871) removed a needle from the heart; this is the first case recorded where any surgical treatment was attempted. Decker reviewed 109 cases of foreign bodies in the heart; these had been reported between 1900 and 1939 The foreign bodies reported form a miscellaneous collection which includes such items as needles, safety pins, nails, iron pegs, hairpins, bullets, shrapnel fragments, skewers, aluminum pipestems, splinters, toothpicks, bone, teeth, and dentures. Iverhardt reported 22 cases of unsuspected needles in the heart.

Pathologic Changes. Borellus (1682) described a lesion of the cardiac muscle with hemopericardium which resulted from a shot which did not perforate the pericardium. Elkin (1936) reported that 2 per cent of all penetrating wounds of the chest injured the heart. However, he commented that, if those who died before reaching the hospital were counted, the percentage would probably be much higher. The right ventricle is most frequently wounded because of its anterior position. Small puncture wounds of the heart at first show hemorrhage of the epicardium and myocardium with clot formation. Within 5 days, the clot is covered by a layer of cells, shortly afterwards organization of the clot is completed and the thrombus is covered by epicardium.

In the myocardium, there is effusion of blood in the vicinity of the wound, and the muscle fibers are pushed apart, this causes degeneration. Within the first 24 hr the gaps between the edges of the wound are infiltrated with fibrin and leucocytes There is a marked accumulation of leucocytes between the muscle fibers, and from the second to the fourth day granulation tissue forms Shortly afterwards, there is connective tissue in the scar formation

to reestablish sinus rhythm. Frequently, spontaneous reversion occurs, but atrial fibrillation has a tendency to recur and to become permanent. If, after the injury, the heart still has normal sinus rhythm, it is advisable to administer small doses of quinidine sulfate every 3 to 6 hr for the first few days, for the purpose of preventing atrial fibrillation, flutter, ventricular tachycardia, or ventricular fibrillation.

The pain of myocardial contusion is reduced in severity by the administration of *nitrates* and *papaverine hydrochloride,* but the discomfort does not completely disappear. The effects of these drugs are similar to those seen in treating myocardial infarction and, in general, the treatment should be basically the same. The period of bed rest should be from 2 to 6 weeks, depending upon the classification of the patient as a good or poor risk. However, this period is frequently prolonged by injury to other parts of the body The complication of *shock* due to cardiac injury should be treated like that which follows myocardial infarction. The associated traumas require their special surgical or medical treatments but, above all, great care should be taken during convalescence to prevent the development of a *cardiac neurosis.*

Reim stated that, although about 30 per cent of all patients with serious cardiac injuries came to the hospital unconscious and often apparently moribund, one should not question the possibility of their survival. Regardless of the apparent hopelessness of cases of tears and ruptures, surgery should be undertaken. The advice of Beck is sound, that repeated tapping of the pericardial sac should be performed, not only to confirm the diagnosis, but also to relieve cardiac tamponade until surgical intervention is possible In shock and collapse, the heart should not be massaged, but only lightly stimulated, because the areas of injury may be extended by fresh hemorrhages. Cardiac massage, although sometimes successful, may be only temporarily so, and can produce myocardial contusions. Therefore, it is safer to use instrument percussion, electrical stimulation, or intracardiac injection. Fractures of the thoracic bony cage with deformities that decrease the anteroposterior diameter of the chest should be corrected so that they do not cause compression or displacement of the heart. Posterior mediastinal hemorrhage occasionally requires surgical intervention to prevent adhesions with cardiac fixation. Steinberg states ". . . that the mere presence of an aneurysm is not an indication for operation Surgery should be restricted to patients who require relief of symptoms or have evidence of enlargement of an aneurysm."

PROGNOSIS

While *valvular rupture* is not associated with sudden death or usually fatal, it must nevertheless be considered as a serious type of injury. *Traumatic insufficiency of a valve* produces a sudden strain on the chamber behind the valve, whereas, in insufficiency produced by disease, the strain is produced gradually. This sudden strain does not allow sufficient time for hypertrophy of the myocardium, and failure follows rather rapidly. The duration of life is, therefore, shorter in rupture of the aortic and mitral valves. Fatal *emboli* may occur, with or without sudden death, from a focus of fibrin or small blood clots on the torn valve leaflets. The healing process in minor injuries to the valve cusps, such as hemorrhage, may later produce an incompetent valve. However, the majority will recover with only slight, if any, damage. The prognosis becomes grave if these valvular injuries are complicated by an inflammation of the endocardium, myocardium, or pericardium.

In *myocardial contusion,* the gravity of the prognosis depends upon the number and extent of the lesions. There is, however, a definite tendency toward rapid healing, especially if the lesions do not extend too deeply into the heart wall. After the more extensive lesions have healed, myocardial insufficiency frequently becomes apparent. Sudden death from *cardiac rupture* does not always occur, and there are numerous cases reported of patients who have lived for 2 or 3 days. Contusions involving the intrinsic nerve mechanism of the heart frequently produce permanent or immediately fatal arrhythmias. *Tears of the cardiac septa* may heal but, if the bundle of His is involved, the work capacity of the heart is diminished. *Rupture of the atrial wall* is most serious, because the thinness of this wall does not allow the opening to be closed with muscle contraction. It has long been observed that the lowest percentage of sudden death is in rup-

ture of the left ventricle. Death, however, depends upon the size and the speed of the hemorrhage

The small pericardial and subpericardial lesions heal uneventfully, but the more extensive or obliterating types may interfere with cardiac output, thus hastening heart failure *Cardiac fixation* due to adhesions frequently results in permanent disability. *Cardiac tamponade* causes sudden death or rapidly progressing failure The heart can also be embarrassed by clot formation in the pericardial sac from even a small wound Obliteration of the sac by adhesions may result in calcification and an *armored heart* (constrictive pericarditis). A rupture of the pericardial sac which allows blood to escape defeats tamponade and delays death Pericardial injuries heal more rapidly than those of the endocardium The prognosis for partial or even complete recovery in cases of uncomplicated mild and moderate cardiac injury is good Uncomplicated hemorrhages have the best prognosis, certainly better than that of contusion or rupture caused by nonpenetrating injuries which involve more than one chamber.

The juvenile heart has a more favorable prognosis because it is smaller, and children are less likely to be exposed to the bursting type of injury. Anderson reduced the possibilities following myocardial contusion to (1) complete recovery, (2) reduced cardiac capacity, (3) pain on effort, (4) congestive failure, or (5) cardiac rupture.

PENETRATING WOUNDS AND FOREIGN BODIES

Historical Background and Mode of Injury. The wound at present is usually produced by a knife, ice pick, bullet, or fragments of bone, earlier causative instruments were spears and arrows There are many important factors to be considered, e g, (1) the character of the knife blade (was it sharp or dull, blunt-tipped or pointed, round or flat; thin and narrow, or broad and thick), (2) the caliber of the gun and character of the projectile (single or multiple, lead or steel, soft-nosed or hard-jacketed), (3) the distance traveled by the lethal object and the angle at which it entered the body.

A penetrating wound of the heart may be caused by a bony fragment, fractured rib, or the sternum, in these wounds there may be no penetration of the thorax. It is also possible to have a penetrating wound of the heart due to a foreign body, such as a needle entering from the esophagus or bronchial tree.

Elsberg believed that wounds which were inflicted during systole bled more strongly than those incurred during diastole. He explained that wounds cut during systole become larger in diastolic relaxation, while those cut in diastole become smaller during systole. Harvey mentioned the case of a stag in which a bullet was found lodged within the heart. Callender (1871) removed a needle from the heart, this is the first case recorded where any surgical treatment was attempted. Decker reviewed 109 cases of foreign bodies in the heart; these had been reported between 1900 and 1939. The foreign bodies reported form a miscellaneous collection which includes such items as needles, safety pins, nails, iron pegs, hairpins, bullets, shrapnel fragments, skewers, aluminum pipestems, splinters, toothpicks, bone, teeth, and dentures. Iverhardt reported 22 cases of unsuspected needles in the heart

Pathologic Changes. Borellus (1682) described a lesion of the cardiac muscle with hemopericardium which resulted from a shot which did not perforate the pericardium Elkin (1936) reported that 2 per cent of all penetrating wounds of the chest injured the heart. However, he commented that, if those who died before reaching the hospital were counted, the percentage would probably be much higher. The right ventricle is most frequently wounded because of its anterior position Small puncture wounds of the heart at first show hemorrhage of the epicardium and myocardium with clot formation. Within 5 days, the clot is covered by a layer of cells; shortly afterwards organization of the clot is completed and the thrombus is covered by epicardium.

In the myocardium, there is effusion of blood in the vicinity of the wound, and the muscle fibers are pushed apart; this causes degeneration Within the first 24 hr the gaps between the edges of the wound are infiltrated with fibrin and leucocytes There is a marked accumulation of leucocytes between the muscle fibers, and from the second to the fourth day granulation tissue forms. Shortly afterwards, there is connective tissue in the scar formation

and usually within 1 to 2 weeks there is no visible trace of the puncture. Punctures of the left ventricle are likely to bleed slightly, whereas those of the atria bleed profusely. The fibrous-tissue healing of the myocardium may be firm or the wall may become thin with formation of an aneurysm. The effusion of blood into the pericardial sac is absorbed rather rapidly, especially if there is no infection to cause either partial or complete adhesive pericarditis. Occasionally, a wound of the ventricles will not completely penetrate the wall and injure the endocardium. However, this does not occur in the atria.

Stab wounds usually have a clean-cut edge, whereas those made by projectiles are frequently jagged and irregular, and have more than one opening. The wound may involve the valves, capillary muscles, chordae tendineae, and the interventricular septum. Valvular trauma may be due to effusion of blood from a nearby wound or dilatation of the valve ring by an aneurysm of the heart. Occasionally, a foreign body will be caught in a valve, a papillary muscle, or chorda. Wounds of the pleura and lungs frequently accompany those of the heart.

The intentional penetrating wounds inflicted during cardiac surgery may produce the same signs, symptoms, pathological changes, and complications as accidental wounds. Contusion of the myocardium or papillary muscles, and rupture of the chordae tendineae have resulted from too vigorous manipulation by surgeons. In these penetrating wounds, the primary cause of death is usually shock, fatal arrhythmias, or hemorrhage. The secondary cause of death is carditis, endocarditis, pericarditis, pneumonitis, pleuritis, embolism, abscess, aneurysm, and exhaustion. *Pericarditis* is probably the most frequent complication of any degree or type of cardiac injury. *Air and other emboli* occasionally cause death, and should be feared in all cases in which the injury or surgery extends into the cardiac cavities. There may be *abscess* formation in the heart wall, pericardial sac, mediastinum, or pleural spaces. *Aneurysms* form in the scar tissue at the site of the injury. Fragments of a fractured sternum or rib occasionally tear the pericardium. This type of injury may be assumed when the tear exactly corresponds to the fracture of the bony cage.

Piercing injuries to the pericardial portion of the thoracic aorta usually lead rapidly to death, because there is no surrounding structure to limit the loss of blood. The short intrapericardial part of the aorta is only occasionally injured because of its position behind the sternum.

It is very difficult to determine whether the transportation of a projectile embolus is ante- or post-mortem. Evidence of fresh dislocation and movement does not necessarily imply that the motion definitely existed before death. Intramuscular movement of a foreign body may be influenced by the position of the body, respiration, muscular contractions, force of gravity, and, to some extent the blood flow, or some combination of these forces. The point of entry of the foreign body is most frequently in the chest; however, it may enter through the esophagus, bronchi, or blood stream via a pulmonary vein, or one of the venae cavae, and migrate to the heart cavity.

Foreign bodies that reach the cavities of the heart may migrate as *projectile embolisms* into the arterial system, or they may become attached to the heart wall by clot formation with fibrosis and calcification. Occasionally a bullet will plug a wound in the heart wall and be surrounded by clot formation and the inflammatory reaction of the endocardium and pericardium. If the foreign body enters from the esophagus or the bronchi, there is invariably an *adhesive pericarditis*. Abscess formation, of course, is always possible at the site of the foreign body, but usually it is encysted or encapsulated by fibrous tissue. The fibrosis surrounding a bullet may resemble a fibroma and become calcified.

Complications. Of the later complications of wounds to the heart, the most frequent are adhesion, obliteration, and calcification of the pericardium. *Mediastinopericarditis* has occurred in a few reported cases. Various disturbances of rhythm such as atrial fibrillation and complete heart block have occurred. *Cardiac aneurysm* may be an occasional complication occurring at the site of the foreign body removal. *Pleural effusion* is almost inevitably a complication, and requires repeated aspiration and even rib resection if an infection develops and cannot be controlled by antibiotics.

Signs and Symptoms. Penetrating wounds of the heart are seldom dry, but are accompanied by profuse hemorrhage which may not be visi-

ble outside of the body. Penetrating wounds of the aorta, venae cavae, or pulmonary vessels are invariably and rapidly fatal.

The diagnosis of injury to the pericardium should not necessarily be difficult, but it is safer to explore the pericardium than to take the chance of an undiagnosed hemorrhage with cardiac tamponade. One should not be misled by the statement that, following the injury, the victim continued great activity for a short time. A significant sign is a wound in the precordial region, but it may be somewhat distant, in which case there is copious hemorrhage Loss of consciousness may be the result of asystole due to hemopericardium or of cerebral anemia resulting from the marked hemorrhage. Muscular twitchings and restlessness may advance to convulsions Frequently, there is a symptom-free period of from 5 to 10 min following the injury, and usually, by this time, *there is a cessation of the bleeding from the* external wound The author would advise against probing, but it is possible in this way to determine whether the heart has been injured (the instrument pulsates) The external hemorrhage may be small, excessive, pulsating, or oozing, or there may be a steady flow. Whether it is arterial or venous blood cannot, as a rule, be determined If the hemorrhage is pulsating, it may have originated in the heart, internal mammary or intercostal artery, or one of the pulmonary vessels, however, absence of pulsation does not eliminate the possibility that these vessels may be injured

When a penetrating wound of the chest involves the pericardium, heart, or great vessels, there is invariably severe *shock* with unconsciousness, cold perspiration, increased respiration, widely dilated pupils, and all the other classical signs The facial expression indicates great distress and anxiety. Frequently, there are signs of air hunger, such as sighing, yawning, and gasping for breath. The pulse is very weak and frequently imperceptible If the blood escapes into the pericardial sac, the anemia is not as pronounced as when it pours into the thorax *Cyanosis*, when it occurs, does so in various degrees depending upon the size of the wound, the amount of hemorrhage, and the extent of its interference with respiration. The venous pressure is frequently increased, and the neck veins are engorged, with extreme dyspnea and marked anxiety. There is a marked drop in arterial blood pressure, and the latter may become unobtainable *Delirium*, taking on a violent form, may follow wounds to the heart, it is probably due to prolonged cerebral anemia resulting from extensive hemorrhage and low blood pressure.

The presence of *pneumothorax* may prevent satisfactory examination of the chest; however, a large area of cardiac dullness would suggest the possibility of hemopericardium. The so-called *spinning-wheel* or *water-wheel murmur* is rarely heard The most precise information is obtained by roentgenographic examination, which reveals the size and immobility of the cardiac shadow and the presence of hemopericardium. It should be remembered, however, that death can also occur from a rapidly developing tamponade which originated from an amount of blood too small to change the contour of the cardiac silhouette. The *electrocardiogram* is frequently normal for several hours following the injury. *Electrokymography* should be of some assistance. The diagnosis of cardiac tamponade is practically certain if there is a rising or high venous pressure and a falling or low arterial pressure together with an absence of cardiac pulsations on fluoroscopic examination Abnormal ballistocardiographic tracings should be somewhat of an aid If the diagnosis is otherwise impossible, aspiration should be performed. Roentgenographic examination will also reveal the presence of cardiac aneurysm or constrictive pericarditis.

Following the healing of penetrating wounds, there are frequent attacks of *precordial pain*. Substernal pain occurs, especially if a coronary vessel was involved by the wound or was tied in the course of the operative procedure. The presence of a foreign body in the heart is frequently discovered only at autopsy. There may be a deep-seated sensation of weight, heaviness, or oppression. When there is inflammation of the pericardium, the pain is acute and cutting in character It may be continuous or periodic, brought on or intensified by exertion and change of position, such as lying down Punctures of the heart cause very little, if any, pain. *Dyspnea*, another frequent symptom, is usually present only on exertion unless heart failure occurs. There are frequent attacks of palpitation, tachycardia, weakness, fatigue, and syncope, with occasional cyanosis.

Every type of *cardiac arrhythmia* may occur

depending upon the site of injury, location of foreign body, and mode and type of reparative or operative procedure. Premature contractions are probably the most frequent arrhythmia. Serial electrocardiograms may show the various changes that are seen in coronary-artery occlusion with myocardial infarction. These changes may be transient or remain permanent. Frequently, the electrocardiogram shows only myocardial change. There may be abnormalities in all leads, involving the various waves of the electrocardiogram and there may be evidence of delay in conduction. The changes may be consistent with, or similar to, those seen in pericarditis, and they frequently suggest an acute pericarditis rather than a lesion of the myocardium. The electrocardiographic picture in acute myocardial injury depends upon the location of the injury. It may serve a purpose in determining the presence of a wound in the precordial region and whether or not the heart is involved, and will give information as to whether or not a coronary artery has been severed, and also the location of the myocardial damage.

Foreign bodies frequently produce morbid symptoms only when the object changes its position due to movement of the heart. Needles, thorns, and other sharp objects which penetrate from the esophagus may remain without symptoms or damage because their progress through the tissue of the heart is slow and an inflammatory process closes the wound behind the object

Small objects, or those that are not of opaque material, can seldom be seen on roentgenographic examination. In order to ascertain whether a foreign body is intracardiac, its shadow should be seen under the fluoroscope to be within the cardiac shadow in the anteroposterior position, both oblique positions, and when the body is flexed from right to left at the waist. Its movement should also be synchronous with that of the heart shadow, not the diaphragm. If the foreign body is free in the heart cavity, it may occasionally be seen to whirl around in an irregular motion. The history and symptoms may suggest a foreign body but the diagnosis is only definitely established [illegible] and [illegible] to [illegible] ign

body in or about the heart. It is remarkable how the movements of the heart may be communicated to a foreign body.

In some patients symptoms occur only when an attempt is made to resume an active normal life. The difference in the consequences depends on the position of the foreign body in the heart. It must always be remembered that the cardiac symptoms may be neurotic in origin.

Treatment. Matas (1921) wrote "The road to the heart is only 2 or 3 cm in length in a direct line, but it has taken surgery nearly 2,400 years to travel it."

Large doses of *antibiotics* should be given immediately, and even injected directly into the pericardial sac in an aggressive attempt to prevent infectious pericarditis However, if infection develops, complete drainage is necessary, and, if at all possible, the patient should bend forward in a position he would assume if he were standing on his head, since this maneuver will cause the ventricle to move forward and the cul-de-sac of Haller will be open. It is safer to do an *exploratory pericardiotomy* than to run the chance of death from cardiac tamponade or hemorrhage. It is doubtful whether the surgeon should ever place his finger in a wound of the myocardium because the muscle is extremely friable and the wound frequently is torn and enlarged. There should be no attempt to separate the pericardial visceral layers in pericarditis; it is preferable to remove a large portion of the pericardium.

Should *ventricular standstill* or ventricular fibrillation occur, immediate gentle massage should be started and a *defibrillator* used Gentle massage should be at the rate of about 40 to 50 contractions per minute. Ventricular fibrillation may be produced by any type of manipulation of the heart, even the placing of a suture, but it can frequently be prevented by the use of *procaine solution* administered both intravenously and topically to the surface of the heart. When ventricular fibrillation is already established, intermittent, regular manual compression may break the arrhythmia Since atrial fibrillation occasionally occurs during the operative procedure, it is wise to administer *Pronestyl* or *quinidine* as a preventative of both the atrial and the ventricular arrhythmias.

In the case of old wounds containing foreign bodies, in which the patient has the appearance of perfect health with no functional disturbance, it is important to consider the psychic elements before definite statements are made. Frequent *neurotic manifestations* develop, depending upon the attitude of the patient toward the knowledge that he harbors a foreign body in his heart. *Psychotherapy* should be directed not only to the patient but also to overanxious relatives and friends, and against ill-advised surgical intervention The question of surgical removal should be weighed very seriously since accumulated experience has shown that most foreign bodies probably become safely encysted and will do no harm. Turner (1941) states, "The fear of infrequent late complications should not be made an excuse for intervention when the patient is symptom-free, and it would be a good rule to leave the foreign body alone unless the heart *continues to rebel* against its presence." If definite symptoms develop or persist, then intervention, of course, should be considered.

Foreign bodies located in the ventricles or near the apex present a much easier surgical problem than those in the atria. If a foreign body in the pericardium is causing symptoms, it can be easily removed with little risk Most surgeons advise the removal of long, thin objects such as needles or wires, and loose objects within the heart cavity; the former because, if they are removed early, usually do not give rise to marked anatomical changes, the latter because of the dangers of pulmonary or systemic embolus Large foreign bodies in the pericardium should probably be removed as early as is practicable This, however, does not pertain to the intramural type Symptoms engendered by foreign bodies usually disappear with their removal

Many penetrating and nonpenetrating injuries caused by projectiles, bomb fragments, and automobile accidents, could have been avoided by the use of suitable protective devices such as plastic armor, and, in the case

... penetrating wounds alone were instantly mortal, especially those of the left ventricle

The prognosis of a penetrating wound is always serious, but many cases are amenable to immediate repair with subsequent recovery. The time of death following a heart wound depends upon the size, and whether the hemorrhage is fast, slow, to the surface of the body, or into an enclosed cavity. Wounds of the atria are usually considered more dangerous than those of the ventricles, and those of the right atrium even more dangerous than those of the left The direction of the wound is important. In an oblique wound caused by a shot or a stab, there is a possibility of valve-like closure due to intracardiac pressure. Furthermore, a trabeculum may place itself against the inner surface of the wound Also, the wound might be placed so that, in systole, it lies against the sternum or the ribs, and is thus compressed and partially closed. It is possible also to penetrate and separate a few fibers and not enter the cardiac cavity; the prognosis in such wounds becomes more favorable Penetration of the great vessels is usually followed by death within a few minutes It is possible for a bullet or a foreign body to close the wound and stop the hemorrhage. Occasionally, it happens that complete collapse may have a favorable influence The prognosis is more grave in bullet wounds because they not only frequently cause two cardiac wounds, but also greater tissue destruction. The postoperative prognosis is dependent upon infection, pericarditis, and pneumonia. Makins believes that death is more often due to cardiac standstill than to hemorrhage.

There are numerous reported cases of foreign bodies that have been tolerated in the heart for a long period of time. There have been reports of soldiers returning to active duty, others have engaged in athletic contests and hard labor after foreign body removal The most favorable prognosis is when the foreign body is in the pericardium, next in the ventricle, and most grave when in the atrium or free in the cardiac cavity. Death following removal is most frequently due to infection, occasionally an embolus or hemorrhage, but seldom cardiac failure. Pneumonia with or without infarction, pulmonary embolism, arterial embolism, pericarditis, pleurisy, septicemia, cardiac failure, and cardiac arrest are also frequent causes of death

AIR EMBOLISM

Air embolisms may be either arterial or venous. The latter result from the rapid entrance of relatively large amounts of air into the venous system, and its subsequent lodgment in the right ventricle, causing an air bubble and thus obstructing the outflow. Arterial air embolism occurs when air enters the pulmonary veins and passes into the systemic arteries. A venous air embolism may also cross an atrial or ventricular septal defect and become arterial. Air emboli reaching the lung from a systemic vein do not cross the pulmonary bed to the pulmonary veins and systemic arteries (Curtillet).

Venous air embolism is most frequently a complication of surgical procedures in areas where large systemic veins are encountered, e.g., in the neck and thorax, and in obstetrical or gynecological procedures Diagnostic procedures such as pneumothorax, pneumoperitoneum, peritoneoscopy, perirenal air insufflation, tubal insufflation, cardiac catheterization, urethroscopy, and nasal sinus irrigation are common causes. Criminal abortion, cesarean section, surgical interference for placenta previa, assumption of the knee-chest position in the early puerperium, and prostatic and breast surgery, have all produced air embolisms Transfusions and intravenous infusions are occasional causes.

Clinical manifestations of venous embolism are shock, dyspnea, tachycardia, pallor, and sudden death. A rapid rise of venous pressure causes marked cyanosis and a loud *churning, or water-wheel murmur*, may be heard over the precordium.

Electrocardiographic changes characteristic of myocardial ischemia have been described and are explained by the work of Visscher, who showed coronary blood flow to be dependent on the pressure gradient across the coronary system. The thebesian blood flow is greatly restricted with the rise in pressure inside the right ventricle and, as the aortic pressure falls, the gradient is markedly reduced The air trapped in the right ventricle obstructs the outflow and eventually causes cerebral ischemia. This type of obstruction may also be caused by widespread embolization of the pulmonary arterioles and capillaries.

Once the diagnosis has been established, immediate therapeutic measures are imperative. The patient should be placed in the left lateral position, thus placing the pulmonary outflow tract in the relatively inferior part of the right ventricle and displacing the trapped air upward. Thus outflow is again established and the air is gradually absorbed (Durant et al.). *Narcotics* and *papaverine* should be given for pain and vasospasm. Inhalation of 100 per cent oxygen has been recommended on the basis of experimental studies by Fine and Fishman If these measures are ineffective, an attempt should be made to aspirate the air by inserting a needle into the right ventricle

Arterial air embolism results when air enters a pulmonary vein and passes through to cause ischemia in such vital organs as the brain and heart. Pneumothorax, thoracentesis, and thoracic and open-heart surgery are the procedures most commonly involved. Rapid ascent, either from ocean depths (*caisson disease*) or to high altitudes, is another cause. Catheterization of the left heart has been known to accidentally cause air embolism.

Various *neurological manifestations*, i.e., coma, convulsions, aphasia, hemiparesis, and others may develop, depending on the cerebral vessels involved. Ophthalmoscopic examination may reveal air bubbles in the retinal arteries. The skin of involved areas develops a marbled appearance. A small skin incision over the superior part of the body may demonstrate air bubbling. Electrocardiographic changes typical of myocardial infarction have been described by Durant (1935).

Therapy is unsatisfactory and mostly supportive. Placing the patient in Trendelenburg position during a procedure in which air embolism is a possibility, may avert cerebral embolization Prophylaxis is definitely the best measure

8

Poisoning of the cardiovascular system

FRANKLIN C. MASSEY

Any material which is detrimental to the normal functions of the living organism is called a "poison" Most substances conventionally used *to maintain and reestablish the physiological or normal status of health may, under certain circumstances, be included in this category* Other substances, never intended for human contact or ingestion, often deleteriously affect the integrity of the healthy organism.

POISONS

A number of *poisons* are properly used as *drugs* (digitalis is perhaps the most *common* of these), while certain common chemicals, such as carbon tetrachloride, were never intended *to have* desirable human applications. *Striking exceptions* to such generalizations include potent compounds like strophanthin, eserine, the mustards, and a host of others, *which* have come into use as drugs (in smaller doses) after having been designated as "poisons."

Poisons, or substances which are noxious to the well-being of the human cardiovascular system, may be further classified as exogenous *or* endogenous.

Snake Venom. Cardiovascular abnormalities due to the proteolytic snake venoms are *rare in the* United States and are usually limited to vascular phenomena. *Hemolysis, alteration of blood coagulability,* and *local necrotizing effects* are characteristic lesions *secondary* to venomous snake bites, besides the neurotoxic manifestations. *Multiple, focal, myocardial hemorrhages* undoubtedly contribute to death due to snake venoms, these are *accentuated* at times by the "spreading" activity *and increased* capillary permeability induced by the potent toxin. In effect, myocardosis, pericardosis (due to hemorrhage), *or both, are produced* by the snake venom Remarkably, intracardiac blood remains incoagulable for up to several hours post-mortem in fatal instances.

Because of the paucity of information on *this subject* in cardiovascular literary sources, *two case histories* are presented here. The first was accompanied by minimal, but probably *significant, ECG* aberrations, and is detailed in conventional fashion:

A 38-year-old colored man was *admitted* to a military general hospital for treatment of *a rattle*-snake bite approximately 24 hr old *He was a carni*val worker, and his occupation involved handling snakes The patient was bitten (by a 2½-ft *rattle*snake) *over the dorsum of the left* thumb and in the web space between the thumb and index finger *He quickly incised* the wounds of the fang punctures with a pocket knife and sucked out the blood himself. *Immediately* thereafter, a tourniquet was applied *around the wrist* by one of the other carnival workers. He was taken to a civilian general hospital *about 1 hr later. A* tourniquet was reapplied at that hospital *and* the patient was given 10 mg of morphine. He *was then* transferred to a county hospital were he received 15 ml of snake antivenin, sedation, *and* Neohetramine in three doses of 100 mg each. His left arm was packed in ice from the finger tips to the axilla A urinalysis

was normal. The patient stated that, since his accident, he had suffered three chills and felt feverish following each chill He also felt nauseated, and had vomited three times.

Physical Examination. On admission to the military general hospital, examination revealed a well-developed, well-nourished colored man who did not appear acutely ill, but who was drowsy and lethargic. The whole left upper extremity, from the finger tips to the axilla, was diffusely swollen, red, tense, and tender. One fang mark was seen over the proximal dorsum of the left thumb, and another in the web space between the thumb and index finger. Both punctures had been cut crosswise by incisions approximately one-fourth inch in length. There was no drainage from these incisions. Blood pressure was 108/80, pulse 84 respiration 20, and temperature 98.6°.

Laboratory Data. Laboratory findings were as follows. hematocrit, 55, leucocytes, 16,700 with 82 per cent polymorphonuclear cells; icteric index, normal, urinalysis normal, except for microscopic examination of the sediment which revealed rare red cells, occasional white cells, and rare granular and hyaline casts. Urinary urobilinogen was normal. The electrocardiogram was abnormal (Fig 16-8).

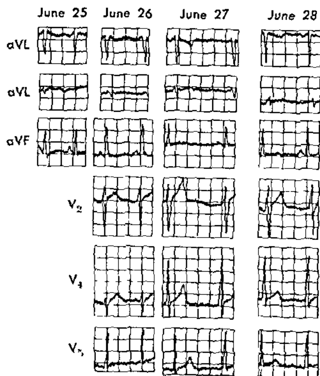

Fig. 16-8. Electrocardiogram of 38-year-old Negro male patient, victim of rattlesnake bite Whether the T-wave variations displayed in these selected electrocardiographic leads have direct myocardiopathologic significance cannot be established unequivocally, but the serial study certainly has merit. (Note especially leads aVF, V_2, V_4, and V_5)

Treatment. The patient was given a booster shot of tetanus toxoid and 1,500 units of tetanus antitoxin. Massive hot wet dressings were applied from the finger tips to the axilla of the left arm The left arm was elevated. Penicillin (50,000 units) was given every 3 hr After 24 hr, there was no essential change. The patient was still nauseated and had vomited once Physical findings concerning the local wound and the involvement of the left arm were essentially the same, except that the edema of the left upper arm had subsided minimally. The patient had remained afebrile, but there was a palpable massive axillary lymphadenopathy.

The second case history is abstracted from a newspaper. Gruesomely fascinating, the account details the generally recognized pathophysiological alterations, but pitifully indicates the lack of perception of the dire possibilities of major cardiovascular complications, including hemorrhagic phenomena of the pericardium or myocardium. A detailed personal medical diary was kept by the 67-year-old victim, the Curator Emeritus of the Chicago Natural History Museum. He had been bitten during the examination of a small tree snake, a South African boomslang. The doctor, himself, was an internationally recognized snake expert.

His account began with a description of the snake and its examination and a conclusion that it was a boomslang because of its behavior when it bit the victim on the left thumb. The reptile had been taken from Chicago's Lincoln Park Zoo to the museum for positive identification. Dr Schmidt's associates said he made the record with no foreboding that he would die He and others at the examination felt he had *not* gotten a lethal dose from the bite and his associates suggested that he make a record of any symptoms that might develop Since the snake was a young one and in captivity for some time, it was thought erroneously that the venom should have been less voluminous and less toxic; the experts erred to the point where use of an antivenom serum was not even considered After being bitten, Dr. Schmidt wrote. "The punctures bled freely and I sucked them vigorously" He reported, "strong nausea, but without vomiting" during an early evening trip by train to his home in suburban Homewood. The next entry, at about 5 30 P.M., said "Strong chill and shaking, followed by fever of 101.7°F., which did not persist. Bleeding of mucous membranes in the mouth began about 4 30 P.M., apparently from the gums."

Three hours later, Dr. Schmidt wrote, he "ate two pieces of milk toast and went to bed." He slept until shortly after midnight, when he awoke, bleeding from the mouth. He reported a good deal of abdominal pain "Took a glass of water at 4.30 A.M.," the diary read, "followed by violent nausea and vomiting" The last entry was made shortly after 7 00 A.M Dr. Schmidt said he had eaten a good breakfast.

The final entry read. "Slight bleeding is now going on in the bowels Mouth and nose continuing to bleed, not excessively." Unattended by a physician, he went into a coma at 2.00 P.M. and, it was estimated that death occurred at about 3 15 P.M. Electrocardiographic and other specific cardiovascular data, of course, were not available.

From a clinical standpoint, the foregoing studies should provide the reader with unforgettable images of (implied) basic pathological abnormalities of the entire cardiovascular system.

Endogenous Poisons. These are chemicals of biological origin, produced within the human host, either by faulty function of a component organ (azotemia, uremia) or by unfortunate residence within the organism of an "opportunist" parasite. In the latter case, they are called *toxins*

A few poisons are biochemicals which are normally present in the human body but cause toxic reactions under abnormal circumstances (lipids?) or in excessive quantity (porphyrins? insulin?) Anions, cations, trace-elements, histamine, and other body substances, may also be included in this group (*see* Part 2, Chap 29)

CHEMICALS

Because of the infinite number of chemicals to which one's cardiovascular system may be exposed, it is impossible to expound knowledgeably on all such situations. It would seem reasonable, profitable, and valid to reflect upon several of the more common chemicals and one or two rather unusual ones

Inorganic Chemicals. While the cardiologically oriented physician might most readily consider the cardiotoxic effects of the heavy metals, especially *mercury*, he must keep in mind such poisons as the trivalent or pentavalent *arsenic*, which are themselves poisons, as are the soluble compounds of arsenic They are extensively used in medicine, as industrial pigments or insecticides. He must also consider the highly volatile chemicals, like *ozone* or the *halogens*

MERCURY. Compounds of mercury are used frequently, both in inorganic and organic preparations. Mercury behaves in vivo as an ion which reacts with *sulfhydryl* groups. Any enzyme featuring a sulfhydryl mechanism may be inactivated readily by surprisingly small amounts of mercury Both aerobic and anaerobic metabolism may be impaired by the mercuric ion Indeed, the union of mercury with a dissociable organic complex forms the basis for very effective diuresis Rapid renal excretion of such organic mercurial compounds assures quantitative accumulation only at the renal site Controlled, reversible poisoning of the renal tubule has been attained by the employment of this otherwise lethal heavy metal (mercury).

Circulating mercuric ion travels in an as yet undisclosed manner. Its deposition in tissue, likewise, is obscure. However, mercury does concentrate selectively in decreasing quantities in the kidney, liver, spleen, intestinal wall, heart, skeletal muscle, lung, and bone

Mercurial poisoning of the heart does *not occur* except with elemental mercury. A remarkable misunderstanding of this fact too often deprives patients of properly prescribed organic mercurial diuretics *Poisoning by inorganic mercury*, with its ability to disrupt myofibril metabolism and to cause "myocardial paralysis," may be counteracted by prompt administration of *BAL* (British antilewisite) and, more recently, by *Edathamil (EDTA)*.

ANTIMONY (STIBIUM). Only one inorganic compound of antimony is used as a drug. As in the case of mercury, substances containing antimony have been used extensively in medical practice, most especially as *emetics* (antimony tartrate) or *antiprotozoal* agents (ethylstibamine)

The *cardiac toxicity of antimony* is heralded first by marked *bradycardia* Electrocardiographically, definite abnormalities are recorded P-wave amplitude increase, *decline in* T-wave amplitude; lengthening of the Q-T interval, and aberrations of the S-T segment While these ECG abnormalities are reversible (and *anticipated* with antiprotozoal thera-

was normal The patient stated that, *since his accident*, he had suffered three chills and felt *feverish* following each chill. He also felt *nauseated*, and had vomited three times

Physical Examination. On admission to the military general hospital, examination *revealed* a well-developed, well-nourished *colored man who* did not appear acutely ill, but *who* was drowsy and lethargic The whole left upper extremity, from the finger tips to the axilla, was diffusely swollen, red, tense, and *tender. One* fang mark was seen over the proximal *dorsum of the* left thumb, and another *in the web* space between the thumb and index finger. *Both punctures* had been cut crosswise *by incisions* approximately one-fourth inch in length. There was no drainage from these incisions. Blood pressure was 108/80, pulse 84, respiration 20, and temperature 98 6°.

Laboratory Data. Laboratory findings were as follows*: hematocrit*, 55, leucocytes, 16,700 with 82 *per cent* polymorphonuclear cells; icteric index, normal, urinalysis *normal*, except for microscopic examination of the *sediment* which revealed rare *red cells*, occasional white cells, and rare granular and hyaline casts. Urinary urobilinogen was normal. The electrocardiogram was abnormal (Fig. 16-8).

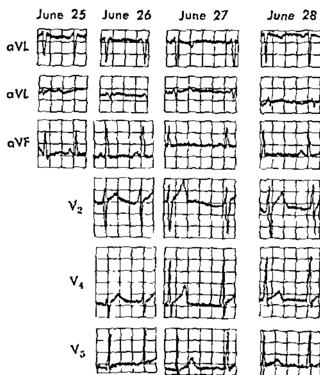

Fig. 16-8 Electrocardiogram of 38-year-old *Negro* male patient, victim of rattlesnake bite Whether the T-wave *variations displayed in* these selected electrocardiographic leads *have direct* myocardiopathologic significance *cannot be established* unequivocally, but the serial study *certainly* has merit. (Note especially leads aVF, V_2, V_4, and V_5.)

Treatment. The patient was given a booster shot of tetanus toxoid and 1,500 units of tetanus antitoxin. Massive hot wet dressings were applied from the finger tips to the axilla of the left arm The left arm was elevated. Penicillin (50,000 units) was given every 3 hr. After 24 hr, there was no essential change The patient was still nauseated and had vomited once. Physical findings concerning the local wound and the involvement of the left arm were essentially the same, except that the edema of the left upper arm had subsided minimally. The patient had remained afebrile, but there was a palpable massive axillary lymphadenopathy.

The second case history is abstracted from a newspaper. Gruesomely fascinating, the account details the generally recognized pathophysiological alterations, but pitifully indicates the lack of perception of the dire possibilities of major cardiovascular complications, including hemorrhagic phenomena of the pericardium or myocardium. A detailed personal medical diary was kept by the 67-year-old victim, the Curator Emeritus of the Chicago Natural History Museum He had been bitten during the examination of a small tree snake, a South African boomslang. The doctor, himself, was an internationally recognized snake expert.

His account began with a description of the snake and its examination and a conclusion that it was a boomslang because of its behavior when it bit the victim on the left thumb The reptile had been taken from Chicago's Lincoln Park Zoo to the museum for positive identification. Dr Schmidt's associates said he made the record with no foreboding that he would die. He and others at the examination felt he had *not* gotten a lethal dose from the bite and his associates suggested that he make a record of any symptoms that might develop Since the snake was a young one and in captivity for some time, it was thought erroneously that the venom should have been less voluminous and less toxic, the experts erred to the point where use of an antivenom serum was not even considered. TABLE 16-2. UNTOWARD CARDIOVASCULAR EFFECTS OF COMMONLY ENCOUNTERED CHEMICALS

Chemical	Cardiovascular effects
Aconite	Cardiac standstill
Atropine	[illegible] blood pressure elevation
Barium compounds	
Benzene	
Caffeine	
Camphor	
Chloral hydrate	Bradycardia, hypotension
Chlorates, bromates, nitrates	[illegible]
Chlorine	
Chloroform	
Cocaine	
Colchicine	
Ergot	
Iodine	
Lead, tetraethyl	[illegible]
Nitrites	
Phosphorus	
Physostigmine	
Salicylates (including aspirin)	[illegible]
Sulfur dioxide	
Thallium salts	
Tin salts	
Tobacco	
Turpentine	Tachycardia and hypotension

rhythm, on the other hand, should be considered *as due to* the disease process and *not* to a drug.

Electrocardiographically, discrete diagnosis of disturbances in the heart rhythm may be obtained, while evidence of conduction aberrations may also be disclosed Intraventricular conduction delay, complete bundle branch block, and lesser degrees of delayed conduction may be encountered as the result of any substance toxic to the cardiovascular system; frequently this includes such drugs as digitalis, quinidine, and procaine amide (Pronestyl).

DIAGNOSIS

Except for miscarried cardiac drug therapy, in which instances the medication is always the first suspect, the diagnosis of poisoning of the heart rests on sound conventional principles.

First, with evidence of cardiovascular malfunction, the more usual pathophysiologic possibilities must be eliminated, of course, the fact that the patient may also have preexisting organic heart disease must not be forgotten An accurate, detailed *history is* essential, particularly when the choice of powerful specific countermeasures is contemplated. The cardiac abnormalities present must logically be those known to be produced by the suspected noxious agent. Misappraisal here can spell disaster.

Once it has been established that probably no other cause for the cardiotoxicity exists, the *singular* therapy indicated may be justifiably initiated *Drugs* tending to aggravate an *already* toxic myocardium must be avoided. A [illegible] will have to be directed at the organism as a whole, rather than at the heart as an independent organ Specific cardiac medication is generally a secondary consideration to the institution of fundamental "antitoxic" measures

RATIONALE FOR [illegible]

The clinical status of the patient's heart will be reflected directly by the extent, nature, and site of any poisoning process involving the cardiovascular *system* directly or indirectly. Whether cardiac functional capacity *remains* intact or is fatally impaired depends on the

peutic objectives) still it must be remembered that the blood vessels are affected seriously all over the body. In the myocardial vascular mesh, this implies *multifocal hemorrhages*. Obviously, then, *myocarditis* other than that of protozoal origin, becomes an absolute contraindication for the use of antimonial compounds.

GOLD. The usurer's mania is prescribed today almost exclusively for the amelioration of rheumatoid arthritis. It has *no outstanding effect on the cardiovascular system;* its toxicity is directed rather, to the hematopoietic system. Whether its pronounced ill effects upon aged and senile persons are due exclusively to gold's acknowledged toxicity to most organs *other than* the heart, is not known, but certainly elderly individuals do not tolerate gold.

SILVER. "Heart disease" due to silver really has nothing to do with cardiovascular disorders. The phrase has been applied to individuals with *argyria*, mistakenly thought to have heart disease because of their cyanotic appearance. Any valid use of silver in medical practice should be limited to local applications only, because of the effective antiseptic and germicidal properties of the silver ion Inorganic salts, usually the nitrate, or organic protein combinations are procurable. Even when silver arsphenamine was widely used, the drug apparently had little effect on the cardiovascular system. The severe *bradycardia* produced by silver compounds injected into animals is apparently of central vagal origin.

PLATINUM. Platinum produces chest distress ("tightness," dyspnea, etc) which requires differential diagnosis to establish pathologic changes in the pulmonary system as the cause, rather than coronary arterial disease or congestive heart failure Also it is necessary to realize that this widely used metal has industrial and social significance in today's environment. At times, the indispensable soluble complex salts of platinum (sodium chloroplatinate) cause enigmatic clinical diagnostic problems of major importance.

Cardiovascular poisoning by platinum is unreported to date, but the importance of this metal to other body systems of the human organism is indisputable.

British anti-lewisite, or *BAL* (2,3-dimercaptopropanol), was developed during World War II for use in the treatment of lewisite poisoning. Besides being an effective antidote for arsenic poisoning, it is also a potent agent against intoxication by other heavy metals, e g, gold, cadmium, and mercury; it is not effective against lead. Evidence of its usefulness has been suggested in poisoning due to antimony, chromium, nickel, copper, zinc, and bismuth Instantaneous administration is imperative, *BAL* must be used *intramuscularly—never intravenously*. It is used as a 10 per cent solution in peanut oil, which also contains 20 per cent benzyl benzoate.

Untoward cardiovascular reactions to BAL itself consist of (1) tachycardia, (2) increased arterial blood pressure, (3) sensations of diffuse warmth, and (4) diaphoresis. Such unwanted side effects are usually dissipated within 30 to 180 min. Their interim amelioration is effected with barbiturates or other symptomatic medication.

CLINICAL ASPECTS

Symptoms. Profound weakness, easy fatigability, and dyspnea on slight exertion tend to be the chief complaints of the patient suffering from any type of "poisoning" of the heart. Essentially, the degree of suffering is related directly to the extent of myocardial involvement, particularly since intoxication of the myocardium affects the heart as a pumping organ.

Precordial discomfort, ranging from an indescribable annoyance to "missed beats," "thumping," or the like, may be experienced if arrhythmias have been produced by the noxious agent. *Anxiety*, associated with any of these complaints, is a complication related largely to the psyche, rather than one produced by the cardiac lesion itself. If *heart failure* is present, naturally the "central" cerebral anxiety tends to be evident.

Objective Findings. Intoxication of the heart can produce all the various clinical signs one would expect with any of the more ordinary pathological changes, i e, congenital, rheumatic, or hypertensive. Disturbances of the normal pacemaker are quite apt to occur, especially minor abnormalities like premature ventricular or atrial contractions In fact, if digitalis is being administered and the rhythm becomes altered after initiation of therapy, the drug, rather than a disease process, should be suspected because it so commonly induces premature contractions or AV block A *triple*

Cardiovascular disturbances in neuromuscular dystrophies

Pathological Aspects
C. GEORGE TEDESCHI

Clinical Aspects
ELWYN EVANS

PATHOLOGICAL ASPECTS

It is generally acknowledged that many anatomically unrelated congenital defects may have a common underlying mechanism in a genetic or prenatal environmental disorder. The association of developmental cardiac anomalies with anatomical defects in other organs and systems is well documented by observations in human beings and by the recent demonstration of a multiplicity of organic defects in the offspring of animals exposed during gestation to varieties of injuries Less clearly understood is the more subtle disturbance that underlies the association of dystrophic disorders in the heart and those in some other organ or system. This sort of relationship is suggested by the high incidence of cardiac alterations in at least two neuromuscular dystrophies. Friedreich's ataxia and progressive muscular dystrophy.

FRIEDREICH'S ATAXIA

Newton Pitt (1887) pointed out heart failure as one of the manifestations of the last phases of a case of Friedreich's ataxia However, when Evans (1942) showed electrocardiographic changes in 12 of 38 patients affected by this disease, it became apparent that cardiac disorders are common in this neurological condition Russell substantiated Evans' observations and showed that the cardiac functional disorder is associated with a structural disturbance, mainly characterized by focal degeneration of muscle fibers; moderate, unevenly distributed inflammatory cell infiltration (lymphocytes, eosinophils, neutrophilic leucocytes); and fibrosis and hypertrophy of the surviving fibers. The Purkinje fibers of the AV node and of the bundle of His were similarly separated by fibrous tissue and inflammatory cells. He concluded that the same agent, possibly of toxic origin, had been responsible for both the cardiac and the neurological lesions Manifestations of cardiac disorder were the patient's major complaints in two cases of Friedreich's ataxia described by Manning In one patient, a 24-year-old man, the heart weighed 705 Gm, in the absence of valvular lesions, coronary artery disease, or any other plausible explanation, the myocardium showed diffuse fibrosis, hypertrophy of remaining myofibrils, and scanty lymphocytic infiltration Since available information indicates that cardiac manifestations occur in approximately one-third of the cases of familial Friedreich's disease, it is conceivable that an inherited lethal gene is responsible for both the cardiac and neural disorders.

PROGRESSIVE MUSCULAR DYSTROPHY

Dystrophic myocardial lesions also occur in progressive muscular dystrophy and they bear a resemblance to the lesions of the skele-

factors listed above. Disruption of the myofibrillar mesh is the key to dysfunction of the heart as an efficient pump. Any toxin, noxious substance, or innocuous material (poisonous because of its excess) will inactivate cardiovascular functions to a degree comparable to the poisoning of other vital organs. The manifold abnormalities of heart disability, from minor ECG aberrations to lethal acute congestive heart failure, are detailed appropriately elsewhere (Part 8, Chap. 9).

The basic principle, then, in approaching the evaluation of the "poisoned heart" is simply to determine whether *each and every myofibril is intact, is affected reversibly, or is permanently damaged.* Sensible therapy is based fundamentally upon accurate appraisal of this problem.

CHOICE OF SPECIFIC CARDIOACTIVE DRUGS

When one is dealing with arrhythmias of the *diseased* heart, two further basic questions arise: (1) is the mere presence of the arrhythmia itself potentially lethal; and (2) is the rapid ventricular rate associated with the abnormal rhythm the important factor which may contribute to increased morbidity, or even cause the death of the patient? Obviously, prior knowledge of the nature of the arrhythmias is necessary in order to make these judgments but, if this is understood, then the problem of treatment is clear and simple.

Choice of Drug. To dispose of the second problem first, if the rapid ventricular rate alone constitutes the threat to life, there is actually no choice of therapeutic agent. There is only *one* cardiac drug (actually, group of drugs) which will decrease the ventricular rate consistently, dependably, and invariably: digitalis.

The problem of cardiac arrhythmias has now been narrowed down to the group in which the arrhythmia itself possesses inherent fatal possibilities. These arrhythmias are predominantly ventricular in origin, i.e., multifocal premature contractions, ventricular tachycardia, or ventricular fibrillation. Other disturbances of rhythm are essentially caused by atrioventricular or intraventricular conduction disturbances and are abnormalities of impulse propagation.

Almost all ventricular arrhythmias can be treated with one of two drugs: (1) *Pronestyl* (procaine amide) and (2) *quinidine*. Pronestyl usually is the drug of choice, most particularly if there is an intraventricular conduction defect, although Pronestyl itself can cause such a change. Procaine amide has the marked disadvantage of being a potent hypotensive drug and must be given parenterally with extreme caution. Quinidine, to be effective, requires doses so large as to induce undesirable side effects. Either drug should be used parenterally *only* with continuous electrocardiographic control, and particular attention must be paid to their extreme propensity for causing delayed stimulus transmission. The marked hypotensive effect of Pronestyl can be combated successfully with pressor agents, like *Levophed* or *Vasoxyl.*

tion, first appears in the *lower* extremities and gradually extends to the rest of the body. The patient tends to walk with a broad base and is unsteady. Spontaneous irregular movements, of the head, shoulders, and extended limbs, occur. Hypotonia or spasticity, and present or absent tendon reflexes, depend upon relative involvement of the posterior columns and the pyramidal tracts. The Babinski and Romberg signs are usually positive. There *may* be skeletal deformities, especially scoliosis. The feet are characteristically shortened, the longitudinal arches high, and toes hyperextended, especially the great toe. Nystagmus and speech disturbances are characteristic. The speech may be slow, scanning, or staccato, and sometimes explosive. Sensory changes are uncommon.

Cardiac involvement in Friedreich's ataxia *is frequent*. Evans and Wright found it to be present in 30 per cent of 38 patients. Manning found heart involvement in four patients with neurological evidence of Friedreich's ataxia, but *found none in two* patients with variants of the disease. Lorenz et al found typical heart involvement in five siblings.

The cardiac symptoms most often described are tachycardia, palpitation, and dyspnea. Definite evidence of *congestive failure* appears in some cases, especially late. Schilero et al mentioned precordial pain and stated that *myocardial infarction* had been noted in one instance. Hejtmancik et al (1949) described two patients with mitral diastolic murmurs confirmed by phonocardiographic tracings. Heart murmurs, including diastolic murmurs, had been described previously by Friedreich and others. Cardiac irregularities and tachycardia have been mentioned frequently and paroxysmal tachycardia or atrial fibrillation occasionally.

Electrocardiogram. The electrocardiogram is frequently abnormal in Friedreich's ataxia. Guillain and Mollaret, Laubry and Heim de Balsac, and others have emphasized electrocardiographic changes, especially changes in rhythm. Electrocardiographic abnormalities were noted in twelve of the 38 cases reported by Evans and Wright, in all four of Manning's patients with obvious neurological findings of Friedreich's ataxia, but not in the two with variants of the disease, and in all five siblings reported by Lorenz et al.

Even the electrocardiogram seemed to show some familial similarities. Lorenz et al commented that the tracings of *five siblings* had a marked resemblance to each other, to those of their father, and to those in the literature. Four of the children showed inversion of the T waves in leads II, III and V_6; one child and the father showed low T waves without significant inversion. Peaked T waves and prominent S waves were present in *all five* siblings, and right axis deviation was present in two. In the literature, ectopic beats, atrial and ventricular, were frequent, paroxysmal tachycardia was not uncommon, and atrial fibrillation was only occasionally mentioned.

Roentgenography. Left ventricular enlargement was noted in 25 per cent of the cases reported by Evans and Wright; three out of four cases reported by Russell, and three out of five cases reported by Lorenz et al. Enlargement of the heart was *frequently noted in the* literature.

Diagnosis. Diagnosis depends upon the recognition of cardiac signs and symptoms in the presence of neurological evidence of Friedreich's ataxia. The hereditary and familial patterns are helpful. Recognition of cardiac involvement depends to a great extent upon the electrocardiographic *picture* of T-wave changes, with or without cardiac irregularities. The absence of a history of rheumatic fever in the patient or family and the absence of left atrial enlargement on fluoroscopy, help rule out rheumatic valvular heart disease, which frequently is suggested by the presence of an apical systolic murmur and occasionally by an apical diastolic *murmur*.

Prognosis. The prognosis in general is poor. The picture may remain stationary for long periods, but the general course *is slowly progressive* to complete incapacity, unless it is cut short by acute myocardial failure or intercurrent infection.

Treatment. There *is no* specific treatment. Myocardial failure, of course, should be *treated* by the usual measures, and occasionally *it may* be *relieved dramatically* by treating an acute tachycardia which *responds* to therapy.

FAMILIAL CARDIOMEGALY

At this point, it may be well to mention the familial cardiomegaly *described* by Evans, who found cardiac enlargement to be familial in *some cases*. Clinically, it was often found fortuitously in *young* adults during routine examinations, or when they were examined

tal muscles Since this is not a disease of great rarity (over 200,000 patients are listed by certain organizations in the United States), and heart involvement is reported in 50 and 85 per cent, respectively, of the cases reviewed in two different series, *the cardiac component of progressive muscular dystrophy must be viewed as a condition of some importance.* There is a general consensus that involvement of the heart muscle plays a role in the course of the disease and that, in many instances, it is responsible for the fatal event.

Cardiac histopathologic changes are nonspecific and depend on the duration and severity of the myocardial lesions. The epicardium and valvular endocardium usually are not implicated and the coronary arteries are not involved. The endocardium lining the ventricles may be slightly thickened, and the myocardium is often scarred in an irregular, patchy manner. Microscopically, individual muscle fibers and bundles of muscle fibers are seen to be entrapped by the proliferated collagenous tissue and the involved myofibrils often show atrophy, vacuolation, and fragmentation. Degenerative changes in the myofibrils may be seen independently of fibrosis, and a few lymphocytes and phagocytic macrophages are often noticed in their proximity. In view of the great similarity of the changes, it can be assumed that the disturbance reflects a systemic dystrophic state of the striated muscle

DYSTROPHIA MYOTONICA

In dystrophia myotonica, abnormalities of the cardiovascular system have received attention, but their significance is not as yet clearly understood The chief abnormality is a disturbance of conduction, either from the atria to the ventricles, or within the ventricles. Carrot et al. have postulated an abnormality at the neuromuscular junction. Londres, in the necropsy of a patient with abnormal electrocardiographic patterns, observed histological changes in the myocardium similar to those in the skeletal musculature. Apparently, this single observation has not as yet been duplicated. Furthermore, Black and Ravin could not find significant deviations from the normal in the hearts of five patients with dystrophia myotonica, who died from several different causes.

CLINICAL ASPECTS

FRIEDREICH'S ATAXIA

Pathogenesis. The basic cause of this disease is obscure; but it is known to be hereditary and often familial. The basic origin of the cardiac involvement is also unknown, however, this too has definite familial tendencies (Evans and Wright, Manning, Lorenz et al.)

Pathologic Changes. There is degeneration of the posterior columns, the pyramidal tracts, and the spinal cerebellar tracts, together with secondary gliosis The spinal cord and the cerebellum may be smaller than usual

Although several authors, including Friedreich himself, described cardiac symptoms and signs, Pitt was the first to emphasize cardiac involvement, and the first to describe myocarditis unassociated with acute terminal illness Russell (1946) described chronic interstitial myocarditis in four patients with Friedreich's ataxia, three of whom showed marked cardiac hypertrophy. Microscopically, there was focal destruction of muscle fibers, fatty degeneration of muscle fibers, and fibrosis and hypertrophy of the surviving muscle fibers. There was some scattered infiltration with small lymphocytes and a few eosinophils and neutrophils Russell mentioned diffuse atheromatous change in the coronary arteries of one patient and slight involvement in another. Congestion and fatty degeneration of the liver and kidneys were mentioned in three instances Schilero et al. stated that the following pathologic picture of the heart was almost invariably present: (1) hypertrophy of all chambers, especially the left ventricle, (2) diffuse interstitial fibrosis of the myocardium; (3) fatty degeneration of the myocardium; (4) round cell infiltration with lymphocytes and eosinophils, (5) normal endocardium and valves; and (6) coronary arteries varying from normal to diffusely atheromatous. They also stated that the following were occasionally seen: (1) pericardial effusion, (2) fibrous pericardial thickening, (3) epicardial petechiae and hemorrhages, and (4) cardiac dilatation.

Clinical Picture. Neurological symptoms usually appear at or near puberty. Ataxia, or incoordina-

pertrophy. The contrast in muscle size and strength is striking Pseudohypertrophy is common in the younger patients, but uncommon in older ones Eventually, most of the muscles are involved, atrophy replaces hypertrophy, and in the late stages, lipodystrophy is frequent, with large deposits of fat about the face, neck, hips, and thighs.

Characteristically, there is weakness and clumsiness The patient has difficulty getting up from a horizontal position, he has to turn face-downward to raise his body on his hands and knees, and then "climbs up on himself." Lumbar lordosis is increased on standing Pain is not prominent. The gait is awkward and waddling. Contractures develop sooner or later in most patients Tendon reflexes are diminished or absent There may be recurrent bouts of fever.

The most prominent cardiac symptoms are related to the cardiac arrhythmias (Zatuchni et al.). Patients may feel well, but then suddenly experience palpitation, feel sick, and break out in a cold sweat, sometimes with associated vomiting, abdominal pain, or a shocklike state. A few patients may be dyspneic, but swelling of the legs is rare Associated myocardial failure tends to be predominantly left ventricular.

Heart size was mentioned clinically in 38 of 94 cases; in six instances the heart was enlarged (Zatuchni et al) Heart sounds usually were of good quality, but the 1st apical sound at times was feeble, and the 2d pulmonic sound, accentuated A systolic murmur was usually present at the base or, especially, the apex. Heart rate or rhythm was mentioned 27 times, the rate varying from 80 to 180 per minute Eight patients experienced irregular pulse or periods of tachycardia.

Boas and Lowenburg studied the heart rate with a cardiotachometer in seven patients, and found the heart rate to be elevated in each during sleep as well as in his waking hours

Technical Studies. ELECTROCARDIOGRAM Observations were recorded in 105 instances reviewed by Zatuchni et al. There was usually a rapid sinus rhythm, although ectopic beats, atrial or ventricular, were not uncommon Two patients had paroxysmal ventricular tachycardia The P-R interval was normal in all but three instances. The duration of the QRS complex was lengthened in three instances, nd the Q-T interval lengthened once. Although Q waves were frequently mentioned in leads II and III, there were no abnormally wide Q waves in any of the 105 cases. Rubin and Buchberg found definitely abnormal Q waves in two cases The Q waves were present in leads I, aVL, and in some of the precordial leads One patient was a 19-year-old boy in congestive failure.

ROENTGENOGRAM. In the cases in which heart size was mentioned, it was usually normal, but not uncommonly slightly enlarged Conspicuous streaking of soft-tissue shadows may be noted in affected muscles (Shank et al).

BLOOD STUDIES. Blood creatine is usually increased, but blood creatinine is normal (Shank et al). The sedimentation rate is usually elevated.

BASAL METABOLISM The B.M.R. is consistently low; the median level for 14 patients was minus 14 5 (Shank et al).

URINALYSIS. The rate of creatinine excretion is less than normal, and that of creatine is greater than normal, especially in boys The ability of the muscles to retain ingested creatine is impaired, and the creatine tolerance is low.

Diagnosis. In most cases, diagnosis of progressive muscular dystrophy is not difficult because of the posture, gait, pseudohypertrophy, impairment of creatine metabolism, lack of a reaction of degeneration, and absence of fasciculation These findings help to differentiate it from the progressive muscular atrophies involving the nervous system. Frequently, congenital heart disease or scoliotic heart disease must be considered in the differential diagnosis because of the age of the patient or the presence of spinal or chest deformities. Zatuchni et al described a 30-year-old patient who was thought to have idiopathic cardiomegaly until the underlying progressive muscular dystrophy was apparent after compensation was established. Occasionally, gastrointestinal symptoms predominate and diagnosis may be difficult if other signs are not present.

Prognosis. The eventual outlook is poor, because atrophy and weakness progress The immediate prognosis depends upon the extent of heart involvement The course is generally more rapidly progressive when the onset oc-

because of cardiac enlargement, minor symptoms, or abnormalities in a routine electrocardiogram.

Findings, including electrocardiograms, were similar to those found in cases of Friedreich's ataxia with cardiac involvement, but without neurological evidence of the disease.

Prognosis in these cases depended to a great degree upon the extent of heart involvement; however, sudden death sometimes occurred from acute failure precipitated by paroxysmal tachycardia.

Manning is of the opinion that these cases probably are examples of Friedreich's disease without neurological manifestation.

PROGRESSIVE MUSCULAR DYSTROPHY

Progressive muscular dystrophy is one of the chronic, progressive, degenerative myopathies; it is characterized by atrophy and weakness of certain muscle groups, creatinuria, and at times pseudohypertrophy.

It is variously classified, depending upon the muscle groups initially and most severely affected, and the presence or absence of pseudohypertrophy, but the main clinical and pathologic features are similar in all forms.

Origin. Other than that the disease is hereditary and familial, the cause is unknown. About 45 per cent of the patients give a history of at least one other member of the family being affected with the disease. Heredity in the pseudohypertrophic form is usually by means of a recessive factor, often sex-linked; heredity in the facioscapulohumeral form is usually by means of a dominant factor. It occurs about three times as often in males as in females.

Cardiac involvement has been considered part of the picture of progressive muscular dystrophy because of its frequent association with this disease and the similarity of the myocardial changes to those of the skeletal muscles (Weisenfeld and Messinger). Globus summarized necropsy findings of the heart in 10 cases in 1922, and Zatuchni et al. reviewed 292 cases of progressive muscular dystrophy reported from 1922 to 1951 and found that 94 were reported to have some cardiac abnormality. Rubin and Buchberg stated that the heart was involved in about 50 per cent of their 33 cases. Of 44 cases (Weisenfeld and Messinger), 85 per cent had some clinical evidence of cardiac dysfunction.

Pathologic Changes. Although many structures are involved, the muscular involvement is characteristic: skeletal, cardiac, and gastrointestinal. All four cases described by Bevans showed skeletal, cardiac, and gastrointestinal muscular involvement. The myocardial changes are somewhat similar to those found in the skeletal musculature, so only myocardial changes will be described.

Zatuchni et al. found reports of 19 patients on whom autopsies were performed. The weight of the heart, in the seven instances in which it was recorded, varied from 140 to 600 Gm. Dilatation was present in four, and hypertrophy in one case. Epicardial fat was grossly present in some instances, and at times fat invaded the myocardium. Occasionally areas of heart muscle were replaced by connective tissue. Grayish streaks were usually noted in the ventricular wall, and small fibrotic areas were often seen. Occasionally, the endocardium was slightly thickened. The valves and vessels were not involved in the series of Zatuchni et al., but atheromas of the coronary vessels were mentioned by Bevans and by Storstein and Austerheim.

Microscopically, myocardial fibrosis varied from finely diffuse sclerosis to large areas of scarring. Fatty infiltration was usually present, and edema involved all structures. Muscle fibers varied in size; atrophy predominated, but some fibers were hypertrophied. There was fragmentation and loss of striation. Some fibers were degenerated and replaced by connective tissue. No evidence of specific inflammatory reaction was noted.

Clinical Description. The disease usually appears early in life. Of 44 cases, the first symptoms appeared before the age of 10 in 62 per cent; indeed most of the symptoms appeared before 5 years of age, but in a few instances were delayed until the patient was as old as 50 (Shank et al.).

In the juvenile type of this disorder, the muscles of the shoulder girdle are involved first. In the facioscapulohumeral type, the muscles of the face, shoulder girdle, and arms are involved first. In the latter group, patients have a "transverse" smile because the corners of the mouth cannot turn up. Shank et al. reported macroglossia in five patients of this group. In the pseudohypertrophic type, muscles of the lower extremity are usually involved first, and the calf muscles are large and feel hard because of hypertrophy and pseudohy-

interval was prolonged in 48.3 per cent, QRS complexes prolonged in 11.7 per cent, and low T waves were present in 3.5 per cent. There was one case each (1.2 per cent) of transient atrial fibrillation, transient atrial flutter, left ventricular preponderance, and nonspecific S-T changes. Litchfield described a case with Stokes-Adams attacks which were thought to be due to the onset of an abnormal ventricular rhythm in the course of AV dissociation

ROENTGENOGRAMS Of 85 cases (Fisch), the heart was enlarged in ten; enlargement was slight in three instances, moderate in five, and marked in two

METABOLIC STUDIES The B M R is consistently low, but in eight cases studied in detail by Jacobson et al and by Holland and Hill, there were no other endocrine abnormalities except slightly decreased 17-ketosteroid secretion. The blood cholesterol, radioactive iodine uptake, serum protein-bound-iodine levels, and response to administration of thyroid stimulating hormone (TSH) were consistently normal, so these authors concluded that the low B.M R was extrathyroidal and probably due to reduced muscle mass.

ELECTROPHORESIS Studies reveal a tendency to elevated beta globulins and low gamma globulin, the latter increases upon antigenic stimulation, according to Zimmerman and Rotstein

Diagnosis. Myotonia distinguishes dystrophia myotonica from the other dystrophies or atrophies, as well as from Addison's disease Hypothyroidism with myotonia possibly should be considered, but atrophy and the other laboratory tests should eliminate this Cardiac involvement should be suspected if symptoms of heart disease arise in a patient with dystrophia myotonica, or if there are electrocardiographic changes, especially conduction defects, and particularly AV conduction defects

Prognosis The course is insidiously progressive

Treatment No therapy affects the course of the disease, but myotonia may be fairly well controlled. Cortisone and corticotropin significantly reduced the duration of myotonia in eight of nine patients and virtually abolished it in three. Quinine was less effective but of definite value in relieving the myotonia (Liversedge and Newman).

MYASTHENIA GRAVIS

Myasthenia gravis is a chronic neuromuscular disease characterized by extreme muscular fatigability.

Origin and Pathogenesis. The precise cause of the disease is obscure, although it is known that symptoms result from an interference with the transmission of impulses across the myoneural junction associated with disturbed acetylcholine metabolism.

Pathologic Changes. Pathologically, the most frequent change has been the focal infiltration of striated muscle with groups of lymphocytes (and a few epithelial cells), called lymphorrhages. The first investigators to mention myocarditis as an integral part of myasthenia gravis were Rottino et al. who reported a case of thymoma with myocardial necrosis associated with acute and chronic inflammatory reaction Subsequently, Russell (1953) described myocardial necrosis and inflammation in three of six cases in which the myocardium was studied microscopically, and mentioned the parallelism between myocardial and striated muscle lesions in type and degree. Mendelow and Jenkins studied autopsy material, with special reference to myocardial involvement, in 12 consecutive cases of myasthenia gravis, thymoma, or both, and found histologic foci of myocardial necrosis of varying degrees in six. The pronounced myocardial changes appeared in the only three instances of malignant lymphoma

Clinical Picture. Clinically, myasthenia gravis is characterized by undue muscle fatigability, especially of the ocular muscles Sustained or repeated stimulation causes rapid fatigue Frequently, the muscles of deglutition and phonation and those of the extremities are involved There may be a nasal quality to the voice, and swallowing may be difficult. With the involvement of the flexors of the extremities, foot drop occurs. Involvement of the flexors of the head may cause the patient to have difficulty in raising the head when lying down and necessitate his supporting his head with his hands when sitting Generalized weakness or asthenia was present in 25 of 60 patients reported by Garland and Clark.

Despite the fact that dyspnea and often cyanosis have been prominent in severe and fatal cases of myasthenia gravis, only one significant clinical study has been made with

curs before the age of 5 years. The duration of the illness ranged from 2 to 65 years in 44 cases reported by Weisenfeld and Messinger.

Treatment. There is no specific treatment for progressive muscular dystrophy, but associated myocardial failure or cardiac irregularities should be treated by the usual methods: digitalis, salt restriction, diuretics, and so forth.

DYSTROPHIA MYOTONICA (MYOTONIA ATROPHICA)

Dystrophia myotonica is a chronic progressive disease characterized mainly by myotonia and atrophy of certain muscle groups, and by lens opacities.

Causative Factors. Dystrophia myotonica is a familial disorder with a dominant hereditary characteristic, but the basic cause is unknown. It occurred in six members of one family (Holland and Hill), and in three of six siblings who lived long enough to manifest the disease (Black and Ravin). Glandular dysfunction frequently has been thought to be a factor, but with careful metabolic studies, no such dysfunction could be revealed (Jacobson et al.; Holland and Hill).

Pathologic Changes. The literature has revealed inconstant changes in the central and peripheral nervous systems and in the endocrine glands, except for the testes which have frequently shown atrophy. Testicular atrophy was present in all four cases of Black and Ravin, almost complete in three of them. Striated-muscle changes are characterized by striking atrophy of the muscle fibers. Late changes include fibrosis and fatty tissue replacement. Fisch (1951) stated that, so far as the heart was concerned, anatomic studies were so meager that no definite opinion could be expressed. Of five cases, Black and Ravin found no cardiac changes in three, increased lipochrome pigment in the myocardium in one, and moderate variability in size of myocardial fibers in the other. Fisch and Evans described a case showing moderate fatty infiltration, marked diffuse fibrosis, and scattered hypertrophied muscle fibers with large rectangular nuclei.

Clinical Description. Symptoms usually begin at about twenty to thirty years of age, but may appear earlier. Atrophy is a prominent feature and [illegible] the orbicularis oculi and oris muscles, masseters, sternocleidomastoids, dorsiflexors of the feet, and muscles of the forearms and thighs. Atrophy may be extreme, especially of the sternocleidomastoid. Facial muscle involvement produces an expressionless appearance, the *myopathic facies*. Involvement of the dorsiflexors of the feet causes foot drop. Atrophy becomes generalized as the disease develops; this, and the associated weakness usually are the motivating reasons for seeking medical advice.

Myotonia also is characteristic. A prolonged muscular contraction or delayed relaxation occurs after voluntary, mechanical, or electrical stimulation. Myotonia is usually most pronounced in the muscles of the hand and forearm, although other groups may be involved.

Other characteristics are frontal baldness, testicular atrophy, cataract, and low basal metabolic rate. Cataracts may appear at an early age, and evidence of heredity of this condition may be limited to their presence.

Griffith (1911) is given credit as being the first to focus attention on the heart when he described a patient with bradycardia as low as 36 beats/min. Fisch (1951) reviewed 85 cases of dystrophia myotonica including six of his own patients, and stated that, with few exceptions, in cases in which the heart was involved, there was an almost complete absence of clinical history and the heart was inadequately examined. Only reports in which electrocardiographic data or anatomical or roentgenographic studies of the heart were available, were included in this study. In only 6 of 85 patients were the symptoms of the heart so severe as to be presenting symptoms. In two out of five of Fisch's patients, the presenting symptoms were exertional dyspnea and palpitation, respectively, and in two of Evans' patients (1944), the presenting symptom was exertional dyspnea. Of 85 patients, the pulse rate was below 50 per minute in nine patients and below 60 in four more. The systolic blood pressure was less than 100 mm Hg in 13 patients and less than 110 in 14 more. Only three patients had systolic pressures above 140. Soft apical systolic murmurs, thought to be functional, were mentioned in ten instances, split 1st apical sounds in eleven, and distant sounds in seven.

Technical Studies. ELECTROCARDIOGRAM. Of 85 cases reviewed in the literature, electrocardiograms were found to show some abnormality in 68.3 per cent (Fisch). The P-R

Cardiac dilatation, systolic murmurs, bradycardia, and electrocardiographic changes may occur during an attack.

Technical Studies

BLOOD CHEMISTRY. Biemond and Daniels first found the serum potassium level to be low during spontaneous attacks. Aitkin et al. confirmed these findings, and noted the prompt beneficial effect of potassium administration; however, there has been no constant correlation between serum potassium levels and paralysis Watson and other investigators have observed cases in which paralysis occurred when serum potassium levels were normal, and these were not benefited by potassium administration.

ELECTROCARDIOGRAM. Electrocardiographic changes in familial periodic paralysis are similar to those occurring with hypopotassemia Initial electrocardiographic observations in hypopotassemia were made on patients with familial periodic paralysis (Stewart and Milhorat; Stoll and Nisnewitz), although electrocardiographic changes had been noted previously in conditions causing hypopotassemia.

Bellet et al made extensive studies on 79 patients with hypopotassemia, one of whom had familial periodic paralysis, and confirmed the changes ascribed to hypopotassemia by Holler and other workers There was no pathognomonic pattern, five electrocardiographic patterns were observed. The changes were predominantly in the T waves, S-T segments, Q-T intervals, and U waves. The five patterns of S-T and T-wave changes associated with Q-T–segment prolongation consisted of the following: (1) depression of the S-T segments in varying degrees; (2) inversion of the T waves, (3) T waves of normal amplitude; (4) T waves of low amplitude; and (5) prominent U waves following the T waves. Eighty per cent of the records fell in the first two groups The electrocardiographic changes were immediately reversible following administration of potassium. The U wave was present in 42 per cent of the cases studied.

Diagnosis. Diagnosis depends upon the discovery of hypopotassemia, electrocardiographic changes, or both during episodes of paralysis, and a return to normal with the administration of potassium.

Prognosis. The condition may last for years. *Occasionally*, death may occur during an attack. Sometimes the attacks tend to decrease with age.

Treatment. Treatment consists of oral or intravenous administration of potassium for the acute attacks, and 4 to 6 Gm of potassium chloride orally as daily prophylaxis.

reference to the cardiovascular system (Taquini et al., 1940). This covered 14 patients with proved active myasthenia gravis and the authors recorded venous pressures, circulation times, electrocardiograms, orthodiagrams, and the effect of carotid sinus pressures. They also studied the effect of Mecholyl in ten instances, and the effect of atropine in nine. They had the opportunity of making pathologic studies on one of these patients and on two others, and concluded that there was no clinical or pathologic evidence of heart involvement in the patients studied

Mendelow and Jenkins mentioned that thorough clinical cardiac evaluation had not been made in the 12 cases they studied pathologically because of the certainty of the clinical diagnosis of myasthenia gravis.

Technical Studies. ELECTROCARDIOGRAM. The electrocardiogram was normal in 14 active cases of myasthenia gravis reported by Taquini et al. Of four cases which came to autopsy and in which electrocardiograms were mentioned, two electrocardiograms were normal; one showed depressed S-T segments in leads I and II; depressed T waves in leads I, II, and III, and inverted T waves in lead IV; the other showed diphasic T waves in V_2 and elevated S-T segments in V_1 through V_6 (Mendelow and Jenkins).

BLOOD STUDIES. A curare-like substance has been found in the blood of patients with myasthenia gravis (Wilson et al., 1953).

ROENTGENOGRAPHY. Orthodiagraphic studies of the heart in 14 active cases revealed no abnormalities (Taquini et al.). Chest roentgenograms were mentioned in only one of fourteen cases reported by Mendelow and Jenkins, and these were normal. Roentgenograms may reveal thymic enlargement, but this is often difficult to diagnose unless tomography is used (Harper) Despite the diagnostic difficulties, thymic enlargement should be looked for in each instance

Diagnosis. Diagnosis of myasthenia gravis in typical cases usually is not difficult, but diagnosis in mild cases, especially those with localized symptoms, may be difficult. Diagnosis depends upon awareness of the disease, history of undue fatigability, physical findings, especially of ptosis or nystagmus, and response to medication. Symptoms improve quickly with intramuscular or intravenous administration of neostigmine or intravenous injection of Tensilon.

Prognosis. Prognosis, in general, is relatively poor. Of 202 patients followed for periods of 1 to 34 years, 32 per cent died within an average of six years after onset of symptoms, but 25 per cent had complete or nearly complete remissions lasting up to 17 years (Grob). Patients who have only ocular symptoms by the end of a year after the onset of symptoms are not likely to develop other evidence of the disease (Grob; Garland and Clark; Ferguson et al.).

Treatment. Medical therapy of myasthenia gravis at present utilizes neostigmine with ephedrine and occasionally quinidine or atropine. Infections should be treated strenuously and sedatives should be used cautiously The value of thymectomy and x-ray therapy is questionable (Vietz). Thymic x-ray therapy followed by thymectomy is thought to be of value (Williams, 1952.)

PERIODIC FAMILIAL PARALYSIS

Periodic familial paralysis is a hereditary and familial disease characterized by recurrent attacks of flaccid paralysis affecting the muscles of the extremities and trunk.

Origin. Other than the hereditary factor, the cause of the disease is not known, it is known to be associated with abnormal potassium metabolism and possibly abnormal carbohydrate metabolism, both of which affect muscle cells. About 80 per cent of the cases of periodic paralysis are definitely familial, but similar spells may be precipitated by conditions which lower serum potassium levels and by metabolic disturbances such as hyperthyroidism (Kepner).

Pathologic Changes. No anatomic abnormalities have been described

Clinical Description. Symptoms usually begin during the first or second decade of life. The attacks of paralysis are flaccid, involving the skeletal muscles beginning in the extremities and moving to the trunk Typically, the patient awakes during the early morning hours and finds he is unable to move. Attacks last, on an average, 6 to 8 hr, but may be shorter, or last several days

Characteristically, there is depression or loss of deep reflexes, normal sensory perception, and no loss of consciousness during attacks Patients feel well between attacks.

Cardiac dilatation, systolic murmurs, bradycardia, and electrocardiographic changes may occur during an attack.

Technical Studies

BLOOD CHEMISTRY. Biemond and Daniels first found the serum potassium level to be low during spontaneous attacks Aitkin et al. confirmed these findings, and noted the prompt beneficial effect of potassium administration, however, there has been no constant correlation between serum potassium levels and paralysis Watson and other investigators have observed cases in which paralysis occurred when serum potassium levels were normal, and these were not benefited by potassium administration

ELECTROCARDIOGRAM. Electrocardiographic changes in familial periodic paralysis are similar to those occurring with hypopotassemia Initial electrocardiographic observations in hypopotassemia were made on patients with familial periodic paralysis (Stewart and Milhorat, Stoll and Nisnewitz), although electrocardiographic changes had been noted previously in conditions causing hypopotassemia.

Bellet et al made extensive studies on 79 patients with hypopotassemia, one of whom had familial periodic paralysis, and confirmed the changes ascribed to hypopotassemia by Holler and other workers. There was no pathognomonic pattern; five electrocardiographic patterns were observed. The changes were predominantly in the T waves, S-T segments, Q-T intervals, and U waves The five patterns of S-T and T-wave changes associated with Q-T–segment prolongation consisted of the following: (1) depression of the S-T segments in varying degrees; (2) inversion of the T waves, (3) T waves of normal amplitude; (4) T waves of low amplitude; and (5) prominent U waves following the T waves. Eighty per cent of the records fell in the first two groups The electrocardiographic changes were immediately reversible following administration of potassium. The U wave was present in 42 per cent of the cases studied

Diagnosis. Diagnosis depends upon the discovery of hypopotassemia, electrocardiographic changes, or both during episodes of paralysis, and a return to normal with the administration of potassium

Prognosis. The condition may last for years Occasionally, death may occur during an attack Sometimes the attacks tend to decrease with age.

Treatment. Treatment consists of oral or intravenous administration of potassium for the acute attacks, and 4 to 6 Gm of potassium chloride orally as daily prophylaxis.

Cardiovascular manifestations of endocrine and metabolic diseases

GROSS AND MICROSCOPIC CHANGES OF THE HEART AND VESSELS IN DISEASES OF THE ENDOCRINE SYSTEM

THYROID GLAND

Hyperthyroidism. Tachycardia, increased cardiac output and blood velocity, and widened pulse pressure are common features of hyperthyroidism; they are related to the higher demand for blood created by the increased metabolic requirements. In thyrotoxicosis, cardiac activity is particularly exaggerated by exertion and excitement. It seems certain that the increased activity of the heart is due, at least in part, to a direct effect of the thyroid hormone on the myocardium. It has been shown that thyroxin forces the metabolism of muscle into aerobic channels, requiring greater direct consumption of oxygen. As a result of this, cardiac and skeletal muscles contain decreased amounts of glycogen (Menne et al.) and probably are depleted of other chemical stores In hyperthyroidism, cardiac muscle appears to be more sensitive to certain stimuli. For example, the sensitivity of cardiac muscle to epinephrine and other vasoactive drugs is increased in animals treated with thyroxin (Hoffman et al.). Atrial fibrillation is common and has been attributed to increased excitability of the atrial musculature.

Cardiac failure in the young, and otherwise healthy, hyperthyroid patient is not common, in spite of the exorbitant demands upon the heart. Myocardial insufficiency will develop more frequently in older patients, especially when the disease is protracted and the cardiac reserve has already been diminished by other diseases These numerous physiological and clinical manifestations of hyperthyroidism should theoretically be accompanied by important morphologic changes in the heart.

Post-mortem studies of the heart in hyperthyroidism and thyrotoxicosis are made difficult by superimposed complicating illnesses, agonal and post-mortem changes, and the effects of therapy. Older studies pointed to a variety of lesions. These include: hypertrophy

and dilatation, focal myocardial necroses, small scars and interstitial fibrosis, lymphocytic infiltration, true myocarditis, and fatty degeneration Weller et al studied the hearts of 35 patients who had had exophthalmic goiter. They failed to observe any gross or microscopic pathological change which was not equally represented in a carefully matched control series There was, however, a relatively higher incidence of myocardial fibrosis, endocardial sclerosis, and cellular infiltration Hypertrophy of the myocardium, fatty ingrowth, fatty degeneration, and arteriosclerosis were common in this series but not more frequent than in the controls In a large series of nodular nontoxic goiter, these workers failed to observe any differences from the controls

Friedberg and Sohval also found no characteristic changes in 27 hearts of patients with *Graves' disease* Hypertrophy was present in more than 50 per cent of the cases but could be explained on the basis of hypertension, coronary *sclerosis*, *atrial fibrillation*, and congestive heart failure *Numerous other studies* confirm the presence of cardiac hypertrophy in approximately 50 per cent of *the cases. It* is of interest that thyroid hormone has been found to sensitize the heart muscle to growth hormone and that the latter is *essential for* the development of cardiac hypertrophy (Beznak and Hajdu) However, according to Friedberg, the cardiac hypertrophy is minimal or absent in uncomplicated cases of Graves' disease, probably *because* of the normal stroke output and diastolic tension It is of interest that the incidence of myocardial infarction *in* thyrotoxicosis is low and that an *increase is* noted when the thyroid state is restored to normal (Jeffers et al.) Injections of thyroxin *into* rabbits and guinea pigs failed to induce specific changes in the myocardium (Menne et al, Rake and Mc Eachern, Andrus). The depletion of glycogen in and fatty degeneration of the myocardial fibers, early interstitial fibrosis, and mild histiocytic *infiltration* observed in these animals, were attributed to the excessive work load thrown *upon* the heart rather than to a direct effect *of thyroxin*

In hyperthyroidism, the plasma total cholesterol (C) is generally somewhat decreased and so is the plasma lipid phosphorus (P). The C/P ratio remains *within* the normal range (Gertler) Other studies have shown that there is an inverse correlation between the basal metabolic rate and serum protein–bound iodine concentration, on the one hand, and the clinically demonstrable incidence of aortic and peripheral arteriosclerosis, on the other. However, no definite relationship was observed between the serum cholesterol concentration and medial arteriosclerosis (Kirk et al).

Experimentally, it has been shown that the thyroid hormone, iodides, and thiocyanates are inhibitors of atherogenesis The mechanism (or mechanisms) by which these substances act is poorly understood but apparently it is not necessarily *through a reduction in* blood cholesterol In this respect, it is of interest that thyrotropic hormone *lowers blood cholesterol* but enhances cholesterol-induced *atherogenesis* (Katz and Stamler).

In conclusion, hyperthyroidism will often induce cardiac *hypertrophy through* overwork and, less commonly, other nonspecific changes of the myocardium, apparently as a result of hypoxia (Raab, 1953). There is no definite evidence that hyperthyroidism might decrease *the severity* of atherosclerosis

Hypothyroidism. The so-called *myxedema heart* was first recognized clinically by Zondek (1918). *Among* the features associated with *this* condition are enlargement of the heart, *slow pulse* rate with normal or low blood pressure, *distant heart* sounds, and electrocardiographic changes, particularly a tendency to low voltage.

Other abnormalities observed in *myxedema* are reduction of cardiac output, prolongation *of* circulation time, and reduction in plasma *and blood volumes (Andrus; Morris and* Blumgart). With specific therapy, the heart *size is* reduced and the electrocardiogram *returns to normal* It seems likely, however, that in *myxedema* both reversible and irreversible cardiac changes may develop, since in some instances *thyroid* therapy failed to modify the cardiac manifestations (*Holzmann*).

The anatomic changes of the heart in myxedema, although *studied* by many investigators, are still a subject of debate Older studies (1888) reported the heart to be *hypertrophied, flabby*, and dilated, microscopically, the *presence of swollen*, abundant interstitial connective *tissue with* a great excess of mucin was noted Dilatation of the heart and degenerative changes *in the* myocardium, char-

It seems certain that the increased activity of the heart is due, at least in part, to a direct effect of the thyroid hormone on the myocardium. It has been shown that thyroxin forces the metabolism of muscle into aerobic channels, requiring greater direct consumption of oxygen. As a result of this, cardiac and skeletal muscles contain decreased amounts of glycogen (Menne et al.) and probably are depleted of other chemical stores In hyperthyroidism, cardiac muscle appears to be more sensitive to certain stimuli. For example, the sensitivity of cardiac muscle to epinephrine and other vasoactive drugs is increased in animals treated with thyroxin (Hoffman et al.) Atrial fibrillation is common and has been attributed to increased excitability of the atrial musculature.

Cardiac failure in the young, and otherwise healthy, hyperthyroid patient is not common, in spite of the exorbitant demands upon the heart. Myocardial insufficiency will develop more frequently in older patients, especially when the disease is protracted and the cardiac reserve has already been diminished by other diseases. These numerous physiological and clinical manifestations of hyperthyroidism should theoretically be accompanied by important morphologic changes in the heart.

Post-mortem studies of the heart in hyperthyroidism and thyrotoxicosis are made difficult by superimposed complicating illnesses, agonal and post-mortem changes, and the effects of therapy. Older studies pointed to a variety of lesions These include: hypertrophy

Of particular interest are the previously mentioned changes (described first by Kountz and Hempelmann) in the ascending and abdominal portions of the aorta. This lesion consists of an accumulation of amorphous metachromatic basophilic material between the muscular and elastic fibers of the media, and is not associated with an inflammatory reaction In some cases, it was followed by *dissection and rupture of the aorta* The degree of the lesion is proportional to the duration of athyroidism.

Recently, an irregular thickening of the capillary walls in the myocardium was observed in cases of myxedema This change, however, has no correlation with either the duration of myxedema or treatment with thyroid hormone, and a similar thickening was also observed in instances of hypertension and inflammation (Baker and Hamilton). It is not clear whether this morphologic change is related to the markedly increased capillary permeability of myxedema (Lange).

The occurrence of *pericardial effusion* in myxedema has been observed both clinically and at autopsy, even in the absence of cardiac failure (Gordon, Feasby, Lerman et al ; Kern et al) It has also been reported as a development in thyroidectomized rabbits (Webster and Cooke) but not in those with myxedema induced by I^{131} (Kurland et al). This effusion has been found to contain cholesterol in a concentration of not over 20 per cent of the amounts present in the blood

ANTERIOR PITUITARY GLAND

Hyperpituitarism; Acromegaly Cardiac hypertrophy, involving especially the left ventricular myocardium, is a common feature of acromegaly in association with generalized splanchnomegaly (Courville and Mason). The weight of the heart may range from 500 to 1,300 Gm (Humphrey and Dixon, Cushing and Davidoff, Hejtmancik et al , 1951). There is some dispute as to whether there is an increase in the number or in the size of individual myocardial fibers. According to some authors, cardiac enlargement in gigantism is proportional to general body growth, but is far above the expected weight in acromegaly (Levene and Miller). Coronary atherosclerosis is common and is frequently associated with myocardial infarcts, fibrosis, and calcification. Dilatation of the blood vessels, and especially of the aorta, has also been mentioned.

Various factors have been suggested to explain these pathological findings. Hypertension is frequently found in acromegalic patients (Bartelheimer) and at times can be extremely severe (Zondek, 1920). It has been attributed by some to a concomitant hyperfunction of the basophil cells of the anterior pituitary gland but convincing evidence for this is lacking. The frequently associated hyperthyroidism and heart failure have also been held responsible, but the degree of cardiac hypertrophy is usually greater than might be expected from these causes alone. Diabetes mellitus is probably responsible in part for the severe degree and early appearance of atherosclerosis. It is apparent that the most important factor responsible for cardiac hypertrophy, in addition to hypertension, is the excessive production of growth hormone. Some experimental evidence strongly supports this view (Selye; Raab). As far as the other myocardial changes are concerned, these must be attributed to coronary insufficiency caused by atherosclerosis and the disproportion between myocardial mass and coronary flow.

Hypopituitarism; Simmonds' Disease. The main findings in the cardiovascular system in autopsies of patients with hypopituitarism are (1) *brown atrophy of the heart,* which is observed in about one-third of the cases; and (2) absence of a significant degree of arteriosclerosis (Ruggieri). This is in sharp contrast with the findings in hyperpituitarism where hypertrophy of the heart and severe arteriosclerosis are the rule

In extreme hypopituitarism, the heart may show changes similar to those found in myxedema (Cluxton et al); these consist of vacuolar degeneration of muscular fibers with basophilic degeneration of the cytoplasm and interstitial fibrosis (Dailey et al.).

THE ADRENAL GLAND

Hypercorticism; Cushing's Syndrome. The association of increased blood volume, hypertension, polycythemia, hypercholesterolemia, and diabetes mellitus, are some of the important features of Cushing's disease that might enhance the development of cardiovascular lesions.

The heart is generally hypertrophied, and

acterized by (1) loss of transverse striations, (2) granular disintegration, and (3) cloudy swelling of muscle fibers, were also observed. Schultz ascribed a peculiar infiltration of mucoid substance and a thickening or swelling of the aortic valve to the same cause. This interstitial material was homogeneous and stained bluish with hematoxylin, but differed in its staining properties from the myxedematous infiltration of the skin. Fishberg (1924) pointed out the frequency of coronary arteriosclerosis, small myocardial scars, and hypertension. All these factors may lead to myocardial insufficiency and, therefore, play an indirect role in the pathogenesis of heart failure in myxedema. Higgins mentioned that only five autopsy records at the Massachusetts General Hospital in Boston indicated myocardial changes of the heart in myxedema. In four of them, the changes consisted of interstitial edema and fibrosis; in the fifth, of fibrosis only. He believed that a *mucoid infiltration* of the myocardium appears early in myxedema, and that this is followed by further degenerative changes, coronary sclerosis, and interstitial fibrosis La Due (1943) observed marked hydropic degeneration of the sarcoplasm of the muscle fibers. Edematous material was also present between the muscle fibers, especially beneath the endocardium White believes that the enlargement of the heart in myxedema is due in part to dilatation and in part to the "myxedematous" changes in the myocardium. Means states that the heart is grossly edematous, leading to a condition of pseudohypertrophy. Brewer studied the nature of the mucoid infiltration of the heart by histochemical methods He noted that this material is PAS [1]-positive but is more resistant to digestion by hyaluronidase than is similar material observed in other tissues Foster and Barr, and several other investigators, noted lesions of muscles (including the myocardium), characterized by degeneration of the central portion of the sarcoplasm with the production of vacuoles containing a basophilic and granular material. This material was thought to be "fibroblastic mucoid" and considered similar to that seen in idiopathic cystic necrosis of the aorta, and in the aortic lesions observed by Kountz and Hempelmann in cases of induced hypothyroidism. Fisher and Mulligan conducted a quantitative and correlative study between basophilic degeneration of the myocardium and atrophy of the thyroid gland. They found considerable more basophilia of the muscle fibers in patients with atrophy of the thyroid gland than in a miscellaneous group of control cases Means has emphasized that one must distinguish sharply between the pathologic findings in treated and untreated patients. Typical changes of myxedema are found in untreated cases only.

In experimental myxedema, Webster and Cooke observed changes similar to those described by Foster and Barr. Other investigators (Brooks and Larkin; Goldberg, 1927), however, failed to observe these changes. The severity and duration of hypothyroidism are probably important in this respect.

An early incidence of atherosclerosis, apparently because of hypercholesterolemia, has been noted in patients with myxedema However, the associated increase in phospholipids may compensate for the elevated serum cholesterol. Friedberg found little support for the theory that myxedema predisposes human beings to atherosclerosis, a concept which he thinks has developed from the experimental evidence that atherosclerosis can be produced and enhanced by thyroidectomy (Goldberg). It has been the experience of some pathologists (Milles), however, that, as a rule, women who had undergone a thyroidectomy many years before presented at autopsy a greater degree of atherosclerosis than other women of comparable age. It is interesting (Bruger and Rosenkrantz) that the incidence of hypometabolism in subjects 55 years of age or older is greater among those exhibiting clinically detectable arteriosclerosis than among those without arteriosclerotic manifestations On the other hand, it has been reported (Blumgart et al) that the incidence of atherosclerosis is not greater than normal in myxedematous patients and that, in the absence of hypertension and cardiac hypertrophy, it is of only moderate degree (Baker and Hamilton). In one clinic, approximately 25 per cent of the patients with myxedema also had hypertension; and probably this is the most important single factor in enhancing atherosclerosis (Hamilton and Greenwood).

[1] Periodic acid Schiff staining procedure for mucopolysaccharides.

in adults with pheochromocytomas (Cahill; Kremer, Hueper). In several cases, however, no significant vascular changes were detected at autopsy (Green; Palmer and Castleman).

It should be noted that protracted administration of epinephrine to experimental animals tends to induce necrotizing and calcifying lesions, especially in the media of small arteries. Atherosclerosis is not a common finding in these animals, unless a high-cholesterol diet is administered simultaneously (Anitschkov; de Suto Nagy and Waters). It would appear, however, that hypertension per se is the most important factor in the pathogenesis of the arteriosclerosis observed in patients with chromaffin tumors of adrenal glands

PARATHYROID

Hyperparathyroidism. The cardiovascular manifestations of hyperparathyroidism are represented by (1) a tendency toward hypertension, in most cases on the basis of secondary renal involvement, and (2) by electrocardiographic changes related to hypercalcemia. Morphologically, the only significant lesion observed in the heart is the presence of *areas of calcification* in the myocardium (Allbright and Reifenstein, 1948). Although calcification of arterial walls is common, arteriosclerosis does not appear to be an important complication, at least in primary hyperparathyroidism Similarly, the cardiac lesions are not functionally significant (Raab).

Hypoparathyroidism. No significant morphologic changes have been described in the cardiovascular system of patients with hypoparathyroidism *Precordial pain* and *sudden death,* which occasionally occur in patients with tetany, are attributed to hypocalcemia and to the increased sensitivity of the heart and arteries to epinephrine (Raab).

PANCREAS

Hyperinsulinism and Hypoglycemia. Cardiovascular signs and symptoms are a prominent feature of hypoglycemia, whether this is due to islet-cell adenoma of the pancreas, insulin overdosage in the treatment of diabetes mellitus, or (insulin) shock treatment of schizophrenia Reduction in blood sugar may induce or aggravate hypoxia of the myocardium and precipitate attacks of precordial pain and myocardial infarcts. Some of these clinical features are attributed by some investigators to a compensatory secretion of epinephrine induced by hypoglycemia

Morphologically, no specific cardiac or vascular changes have been attributed to overproduction of insulin. However, in one case (observed by the author) of long-standing hypoglycemia caused by an islet-cell adenoma of the pancreas, death was caused by a *dissecting aneurysm of the aorta* Experimentally, administration of insulin and sugar to rats for periods up to 3 months induced glomerular and arteriolar changes of the diabetic type (Goth et al.).

Diabetes Mellitus. The association of diabetes with atherosclerosis and hypertension is well known. Coronary atherosclerosis, cardiac hypertrophy of moderate degree, and myocardial infarction are common findings at autopsy (Clawson and Bell). Control of diabetes mellitus by insulin, and the subsequent prolongation of the diabetic's life have greatly contributed to the increased severity of atherosclerosis in general and coronary atherosclerosis in particular. The predisposing effect of diabetes is further suggested by the fact that severe coronary atherosclerosis with occlusion is almost as common in diabetic women as in men (Bradley and Bryfogle). Further, coronary atherosclerosis of considerable severity is not uncommon among young diabetics. As a result, the incidence and severity of myocardial infarction are greater among diabetics Diabetic nephropathy, characterized morphologically by a peculiar form of capillary glomerulosclerosis and clinically (often) by the nephrotic syndrome, is an important factor in exacerbating the atherosclerotic lesions through the development of hypertension and of higher levels of serum cholesterol. The type of atherosclerosis observed in patients with diabetes mellitus does not differ from that seen in nondiabetics, except for the greater abundance of lipid deposits in the intima of elastic as well as muscular arteries, and for the frequency and severity of hyaline changes in the arterioles (Warren and LeCompte). No detectable morphological myocardial changes have been reported in association with the abnormalities of severe potassium concentration which occur in diabetic acidosis and its subsequent treatment with insulin (Henderson).

coronary atherosclerosis is severe. These changes are particularly prominent when hypertension is pronounced and is associated with diabetes mellitus (MacMahon et al.; Russell et al.; Ruggieri; Oppenheimer and Silver). Atherosclerosis of both large and medium-sized arteries has been observed, even in young adults and children with this syndrome (Raab, 1953). Heavy and prolonged treatment with cortisone and similar compounds with resulting Cushing's syndrome may induce similar vascular changes.

The possibility exists that the particularly severe form of atherosclerosis and hypercholesterolemia, usually present in patients with Cushing's syndrome (Hueper, 1935; Williams, 1951), may be related to a direct effect of cortisone on plasma lipids (Adlersberg et al., 1951) rather than to the coexistent diabetes mellitus.

There are no definite observations to indicate that androgen administration predisposes to or aggravates experimentally induced atherosclerosis. However, there are many studies indicating a prophylactic and therapeutic inhibition of coronary atherosclerosis by estrogens (Katz et al.). Masculinization and virilism, on one hand, and severe atherosclerosis, on the other, in Cushing's disease emphasize once more the male predisposition for atherosclerosis and the probable importance of sex hormones in this respect.

The few reported cases of *primary aldosteronism* (Conn and Louis) would appear to be associated with cardiac hypertrophy and severe arteriosclerosis.

Hypocorticism; Addison's Disease. The most common post-mortem findings in cases of untreated Addison's disease are (1) the reduction in size of the heart to well below the average normal size and (2) its brown color, i.e., *brown atrophy of the heart* (Addison; Barker; Guttman, Rowntree and Snell). Microscopically, except for atrophy and pigmentation by lipofuscin of the myocardial fibers, no changes of note have been observed in untreated cases (Sorkin).

Following the introduction of desoxycorticosterone acetate in the therapy of Addison's disease, several reports emphasized the presence in the myocardium of *small foci of necrosis* of myocardial fibers, often, but not always, accompanied by infiltration of lymphocytes (Goodof and McBride; Soffer; Sorkin, Sommerville et al.).

The reduction in the size of the heart in Addison's disease is generally attributed to the reduction in blood volume and associated hypotension (Friedberg, 1956). However, the importance of the loss of potassium and water from the myocardium, as well as from other muscular tissue (Zwemer and Truszkowski), cannot be disregarded. In addition, it is known that potassium is important for tissue-protein synthesis. Some of these myocardial changes may be due to the toxic action of sodium ions on cells that have lost a critical amount of potassium (Cannon et al.).

When desoxycorticosterone acetate and sodium are administered in large doses to patients with Addison's disease, sodium and water are retained, with simultaneous excretion of potassium and reduction in serum potassium levels. As a result, both blood volume and pressure are restored to normal or above normal levels, with an increase in size of the heart (Mc Gavack, Currens and White). The rapid loss of potassium from the blood will lead to depletion of the intracellular potassium of the myocardial fibers. The microscopic lesions found in the hearts of these patients are comparable to those produced in rats by the administration of desoxycorticosterone (Darrow and Miller) and by potassium-deficient diets (Follis, 1942; French). Similar changes, namely small areas of myocardial fibrosis and necrosis, have also been observed in patients with a history of hypokalemia due to different causes (Schwartz et al., 1954).

Hyperfunction of the Adrenal Medulla; Pheochromocytoma. Well-differentiated tumors of the adrenal medulla (of the pheochromocytoma type) produce excessive amounts of norepinephrine and epinephrine, with resultant paroxysmal or sustained hypertension. Cardiac enlargement and vascular changes may develop as a consequence. The hypertrophy of the heart predominantly involves the left ventricular myocardium, especially in patients with chronic hypertension (Green; Raab). The reactive capacity of the myocardium to epinephrine probably contributes to the development of cardiac hypertrophy (Raab). Small foci of myocardial fibrosis have been reported (Rothermich). Arteriosclerosis and atherosclerosis are common and fairly severe, especially

involved, with resultant stenosis. The *stenosis of the pulmonic valve* may be of considerable degree, with reduction of the circumference to as much as half of the normal size. The *tricuspid valve is often insufficient, as well as stenotic*. Histologically, the thick endocardium consists of coarse, often hyalinized collagen fibers. The splitting of elastic fibers in the endocardium and vascularization of the fibrotic valves without infiltration of inflammatory cells have also been described Thickening and fusion of chordae tendineae are common. Moderate hypertrophy of the right ventricular myocardium is usually present. Arterial lesions, which can be attributed directly to the effect of serotonin, have not been described (Thorson, Sjoerdsma et al; Isler and Hedinger, Bean et al.). Patients with carcinoid tumors have also been reported to present a higher incidence (33 per cent) of cardiovascular abnormalities than that (9 per cent) observed in a large series of autopsies (Spain).

The pathogenesis of the cardiac lesions is obscure. It would appear certain, however, that serotonin is directly involved Serotonin is normally destroyed in the liver. In the presence of carcinoid metastases to the liver, the blood originating from this organ would have an abnormally high concentration of serotonin when it reaches the right cardiac chambers. No endocardial changes are seen in the left cardiac chambers, where the blood contains little or no serotonin, unless there is a shunt, such as patent foramen ovale. The possibility that these patients might also be relatively deficient in tryptophan, from which serotonin derives, has also been mentioned as a factor involved in the pathogenesis of muscle wasting and skin changes observed in the carcinoid syndrome (Sjoerdsma et al.).

CLINICAL ASPECTS OF CARDIOVASCULAR DISTURBANCES IN ENDOCRINE DISORDERS

The cardiovascular complications which occur in several endocrine syndromes, aside from commanding considerable clinical interest, have a broad significance as valuable guides to a better understanding of many cardiovascular disorders in which more subtle and inconspicuous endocrine mechanisms are at fault

PHEOCHROMOCYTOMA

Catecholamine-discharging tumors of the adrenal medulla or of other parts of the sympathetic nervous system (paragangliomas) represent Nature's most instructive "experiment." They demonstrate the importance of exaggerated catecholamine action, either paroxysmal or sustained, on cardiovascular function and structure The complete and rapid curative effect achieved by timely removal of such tumors adds greatly to the conclusiveness of a reasoning which attributes to the catecholamines an outstanding pathogenetic role in many common diseases of the cardiovascular system. Patients harboring a pheochromocytoma share with an infinitely larger number of individuals such pathological manifestations as a labile or fixed systolic and diastolic hypertension, cardiac hypertrophy, attacks of precordial pain and pulmonary edema, cardiac arrhythmias, renal insufficiency, lesions of the retinal vessels and, in some instances, a high basal metabolic rate. All these phenomena are reversible by early excision of a pheochromocytoma but, in most instances of general sympathetic overactivity ("essential hypertension," "hypertensive" heart disease, etc.), they can be only partially relieved by surgical or medical measures directed against the operative sympathetic nervous system.

The most dramatic and most pathognomonic clinical signs of pheochromocytoma are *hypertensive paroxysms* According to a prevalence of either norepinephrine or epinephrine, there is (besides high systolic pressure elevations) either a rise or fall of the diastolic pressure, and either slowing or acceleration of the heart rate The paroxysms last from minutes to hours and may be accompanied by headache, anxiety, precordial pain, pallor, tremor, paresthesias, nausea, rise of temperature, and cardiac arrhythmias (such as extrasystoles, atrial fibrillation and AV conduction disturbances). A "hypoxic" pattern of the electrocardiogram (depressed T and S-T pattern) may persist for days after an attack. Pulmonary edema and fatal ventricular fibrillation or arrest may ter-

GONADS

The severity of coronary atherosclerosis and the incidence of coronary thrombosis are considerably greater in males than in females, especially before the menopause. This is particularly true when there are no complicating factors, such as hypertension or diabetes mellitus. After the menopause, the incidence of coronary atherosclerosis and myocardial infarction rises considerably in women although it is still lower than in man. Surgically induced menopause would also seem to accelerate the development of atherosclerosis (Wuest et al.). The predilection of the male sex for atherosclerosis is explained on the basis of differences in lipid metabolism between the two sexes and on the preventive effect of estrogen on the development of atherosclerosis; the latter view is also supported by numerous experimental observations (Katz et al).

On the other hand, masculinizing tumors of the ovaries are not commonly associated with distinctly greater severity of coronary atherosclerosis. The same is true of the adrenogenital syndrome, unless Cushing's syndrome is also present.

THYMUS

The function of the thymus is unknown and it is not certain that this organ should be classified as one of the endocrine glands However, a close relationship exists between the thymus and many endocrine glands It is known that thymic tumors may be associated with cardiovascular manifestations. Association of *thymic tumors* (or thymomas) with the complete Cushing syndrome, including hypertension, has been described (Leyton et al.) More commonly, thymic tumors are associated with *myasthenia gravis.* Myocardial changes have been observed in many cases of myasthenia gravis and were more severe in the presence of thymoma (Mendelow and Jenkins). They consisted of focal atrophy and vacuolization of the myofibrils with lymphocytic infiltration and occasionally of focal myocardial necroses These changes are not consistently found, and there are many cases of myasthenia gravis where no morphologic changes of note are observed in the myocardium.

Most authors do not recognize the existence of the so-called *status thymico-lymphaticus,* not, in any case, as a morphologic pathologic entity (Greenwood and Woods, Young and Turnbull). Certainly, the pressure of the enlarged thymus on the trachea is a factor of no importance.

However, according to some investigators (Marine; Symmers, 1934), this syndrome of generalized lymphoid hyperplasia does exist and is associated with hypoplasia of the vascular system and of the adrenal glands Sudden death in these patients would be attributed to adrenocortical insufficiency. Clinical and experimental observations on the role of adrenocortical hormones in the destruction of lymphoid tissue certainly suggests a close relationship between adrenal glands and the thymus.

THE CARCINOID SYNDROME AND HYPERSEROTONINEMIA

Thorson and his coworkers have described a clinical syndrome characterized by attacks of atypical bronchial asthma, cyanosis, flushing and telangiectasis of the skin, diarrhea, and right heart failure with anasarca, in association with carcinoid tumor of the intestine accompanied by metastases to the liver. This type of tumor had been previously found to contain large amounts of 5-hydroxytryptamine This substance was determined to be chemically identical with enteramine and serotonin (Erspamer and Asero). Serotonin is produced, not only by carcinoid tumors but also by the enterochromaffin cells from which these tumors derive and which are normally found in the mucosa of the intestinal tract. Serotonin directly affects the smooth musculature of blood vessels, bronchi, and intestine. It can be classified as a hormone because of its widespread action on the body and because the cells from which it originates fulfil the definition of endocrine. In this respect, it is interesting that, in the original description, carcinoid tumors were referred to as endocrine tumors.

The pathologic cardiac changes in patients with the carcinoid syndrome predominantly involve the endocardium of the right ventricle and are of considerable interest. They consist essentially of either diffuse or patchy *endocardial thickening and fibrosis.* The tricuspid and particularly the pulmonic valves are also

Primary aldosteronism, first described by Conn, is a syndrome, caused by the exclusive overproduction of aldosterone, usually from a tumor of the adrenal cortex It is characterized by muscular weakness, paresthesias, polyuria, polydipsia, hypokalemia and hypernatremia, arterial hypertension, and renal arteriolosclerosis, but no edema.

When the diagnosis of hyperadrenocorticism or primary aldosteronism has been definitely established, surgical exploration is indicated in order to rule out malignancy, to remove a neoplasm if one is found, and, in the absence of a tumor or of cortical hyperplasia, to perform subtotal adrenalectomy The latter offers the best guarantee for a more or less complete normalization Pre- and postoperative managements require considerable skill and resemble those mentioned in connection with the excision of pheochromocytomas. Roentgen-ray irradiation or electrical coagulation of the anterior pituitary are sometimes successful but do not eliminate the dangers of recurrence or of a malignancy remaining unrecognized.

HYPOADRENOCORTICISM (ADDISON'S DISEASE, POSTADRENALECTOMY SYNDROME, HYPOPITUITARISM-INDUCED HYPOADRENOCORTICISM)

The clinical signs of prolonged and severe deficiency of adrenocortical function (muscular weakness, pigmentation, anorexia, gastrointestinal symptoms, tendency toward "crises" under stress) have been known for a long time

In cases of general hypopituitarism, the signs of secondary adrenocortical hypofunction merge with those of other secondary endocrine deficiencies (hypogonadism, hypothyroidism) and are usually less severe Hyperpigmentation is minimal or absent.

The cardiovascular complications of hypoadrenocorticism are the reverse of those seen in Cushing's syndrome, and are essentially attributable to the reverse pattern of electrolyte disturbance, namely to a loss of sodium, and consequently to a diminution of vascular sensitivity to the pressor catecholamines of the vascular walls The blood pressure falls below the normal level or, in formerly hypertensive individuals, to near normal values Orthostatic hypotensive episodes occur readily. *The size of the heart is subnormal* (roentgenographic cardiothoracic ratio of 0 40 or less). Heart action is weak but congestive heart failure never occurs. Electrocardiographic changes, if any, consist chiefly of *low voltage*, prolonged P-R and Q-T, and flat or inverted T waves Critical situations arise during stress-induced acute exacerbations, when dehydration, fever, azotemia, hypovolemia, and loss of vascular tonus and reactivity produce a shocklike syndrome which, if untreated, almost inevitably ends in death

The *diagnosis* of adrenocortical insufficiency is based, aside from the above-mentioned clinical features, on the findings of a low blood-sugar level and glucose tolerance curve, hyponatremia and hyperpotassemia; a positive water test (Robinson et al); decreased excretion of corticoids in the urine; and the failure of ACTH to provoke eosinopenia within 4 hr or an increase of urinary 17-ketosteroid excretion within 8 hr (Jenkins et al.).

The *maintenance treatment* of adrenocortical insufficiency requires the lifelong administration of cortisone or hydrocortisone (with or without added desoxycorticosterone acetate) by parenteral or oral route, and extra amounts of sodium chloride (Hills et al). Desoxycorticosterone acetate and sodium chloride are particularly effective in restoring the cardiovascular status to normal but require meticulous supervision because hypertensive elevations of the blood pressure and congestive heart failure with pulmonary edema may be provoked by even a moderate overdosage. Stressful situations require an increase in the cortisone dosage. During the hot season, an additional intake of sodium chloride and desoxycorticosterone is advisable. In cases of crisis, the cortisone dosage must be greatly increased in combination with the intravenous administration of fluids, glucose, and sodium.

Withdrawal of corticoid therapy is sometimes feasible in subtotally adrenalectomized patients, but it should be accompanied and followed for a few days by administration of ACTH to compensate for the inhibitory effect which preceding corticoid administration had exerted upon the pituitary and thus, indirectly, on the functional reserve of whatever cortical tissue may still be present.

PREGNANCY

In normal pregnancy, the circulatory volume is markedly increased through the ninth month.

minate the clinical course. Transient states of renal excretory insufficiency, sometimes progressing to full-fledged uremia, occur even in otherwise asymptomatic cases of pheochromocytoma or in connection with hypertensive paroxysms.

In the earlier stages, the intervals between attacks are often entirely symptomless. Under such circumstances, the diagnosis can be made (aside from pyelogram and perirenal air insufflation) by eliciting a typical attack through the rapid intravenous injection of *histamine* (0.025 to 0.05 mg). The injection should be immediately followed by a rise in the blood pressure to a higher peak than that produced by the cold pressor test (immersion of a lower arm in iced water for 60 sec), but false positive responses may occur. Occasionally, *deep manual massage of the adrenal area* can provoke an attack and reveal the site of the tumor's location.

The sustained type of pheochromocytoma-induced hypertension, developing either insidiously, or gradually between paroxysms, is superficially indistinguishable from ordinary essential hypertension but can be identified by an assay of plasma and urine for augmented catecholamines (Manger et al.; von Euler and Ström) and by a positive response to adrenolytic agents. For example, the intravenous injection of 5 mg of *Regitine* causes a rapid fall of the blood pressure, exceeding 35 mm systolic and 25 mm diastolic. *Benzodioxane* can also be used but may cause an alarming blood-pressure rise in cases of essential hypertension

Atheromatous and arteriolosclerotic vascular lesions with particular involvement of the renal arterioles were commonly found in the past in untreated cases of pheochromocytoma, even in young children. *Cardiac hypertrophy* is frequently seen in both the sustained and the paroxysmal hypertensive syndrome of pheochromocytoma *Coronary atherosclerosis,* although encountered at as early an age as 10 years, is not a regular complication of pheochromocytoma, but degenerative and fibrotic foci not infrequently appear in the heart muscle.

The only decisively effective treatment for pheochromocytoma is *early excision* of the tumor or tumors. Pre- and postoperative administration of dibenamine, Regitine, norepinephrine, and cortisone is necessary to combat the hazards of both excessive blood pressure rises and falls, respectively, which are connected with the surgical procedure. Dibenamine and Regitine also prove useful in giving symptomatic relief from paroxysms as long as the tumor is still in place.

HYPERADRENOCORTICISM

Cushing's Syndrome; Primary Aldosteronism. An overproduction of adrenal sodium-retaining mineralocorticoids, which cause cardiovascular complications, occurs in the presence of adrenocortical tumors (benign or malignant) or of cortical hyperplasia. It also not infrequently occurs without any recognizable changes in the adrenal cortex. Coexistence with a basophilic adenoma of the anterior lobe of the pituitary (Cushing's disease) is not uncommon

Depending upon the types and combinations of corticoids which are produced in excess (mineralocorticoids, glucocorticoids, or androgens), the clinical picture will assume a variety of appearances. Exclusive overproduction of glucocorticoids or androgens, or both, may leave the cardiovascular system unaffected and give rise only to the metabolic features of Cushing's syndrome (trunk obesity, diabetes, striae, osteoporosis) or of the "adrenogenital" syndrome (masculinization). Simultaneous mineralocorticoid overactivity, on the other hand, often causes a very high and stable elevation of the systolic and diastolic blood pressures, even in young children; early development of arteriosclerotic and atheromatous vascular lesions, especially in the kidneys, cardiac hypertrophy; and ultimate progression to congestive heart failure. The electrocardiogram shows, as a rule, the characteristics of "hypertensive" heart disease (left ventricular strain pattern). All in all, the cardiovascular syndrome of hyperadrenocorticism can be diagnosed only by the evidence of somatic glucocorticoid and androgen overactivity and by certain laboratory findings: diminution of sodium in the thermal sweat and saliva, and low serum-potassium values, paralleled by an increased urinary excretion of mineralocorticoids. Because of the technical difficulty and costliness of corticoid determinations, the assay *of 17-ketosteroids in the urine* is frequently used as an indirect, and not always sufficiently informative, criterion of hyperadrenocorticism.

In the nonprogressive phase of the disease, which may extend over many years, it is preferable, however, to administer a merely symptomatic treatment of the cardiac complications.

DIABETES MELLITUS

No specific cardiovascular derangements are attributable to the diabetic state per se, but diabetic individuals exhibit a predisposition to the premature development of arterial hypertension and of atherosclerosis in the heart, extremities, kidneys, and brain

Clinical signs of *coronary sclerosis* are common. They appear (on an average) 9 years after the onset of diabetes. The sex difference in the incidence of coronary heart disease (ordinarily male : female = 4 1) is abolished among diabetics. The *statistical* occurrence of myocardial infarctions and congestive heart failure is higher in diabetic than in nondiabetic individuals. *General arteriosclerosis* in diabetics is distinguished by its severity and early appearance Involvement of the arteries of the legs is said to occur eleven times more frequently in diabetics, while qualitatively the lesions are similar to those of nondiabetics The vascular changes which constitute the clinical picture of "diabetic retinitis" resemble those of malignant hypertension

Treatment of the vascular and cardiac complications of diabetes is similar to the routine management of such conditions However, any overdosage of insulin should be carefully avoided in the presence of cardiac pathology because of the danger of resulting epinephrine discharges. Fat and cholesterol in the diet should be kept to a minimum

The cardiovascular situation in *diabetic acidosis* and *coma* is similar to that in shock, as it progresses into the third, "decompensatory" phase Besides the energetic use of insulin, it should be treated with intravenous infusions of saline or sodium lactate solutions Infusion of norepinephrine is to be recommended when blood pressure has fallen to a critically low level. In contrast to epinephrine, norepinephrine does not interfere with carbohydrate metabolism. Following successful insulin treatment, it is important to watch for signs of hypopotassemia and to combat it through an adequate administration of potassium.

HYPERINSULINISM

"Absolute" hyperinsulinism is caused by the discharge of abnormally large amounts of insulin from benign or malignant tumors of the islets of Langerhans or from their metastases. It manifests itself in the form of attacks of pallor, trembling, perspiration, paresthesias, palpitations, epigastric pain, nausea, ravenous hunger, weakness, and eventual prostration and convulsions, sometimes ending in death. These severe hypoglycemic attacks may be elicited by strenuous exercise or by fasting, or they occur a few hours after carbohydrate-rich meals They are caused jointly by the acute hypoglycemia and the secondary massive discharges of epinephrine from the adrenal medulla. Accordingly, there is an increase of systolic pressure, pulse pressure, heart rate, and cardiac output Depression of the S-T segment with flattening or inversion of the T waves, extrasystoles, atrial fibrillation, and precordial pain are observed, especially in elderly individuals. They correspond to the side effects elicited by insulin-shock therapy in mental patients. Milder symptoms of a similar kind have been noted in abnormally sensitive persons during the postprandial hypoglycemic phase

Unless the tumor can be removed surgically, it is necessary to avoid situations provoking hypoglycemia and to adhere to a low-carbohydrate, high-protein diet, with enough fat for caloric requirements, distributed in five or six small meals over the day. However, if an attack is under way, the immediate intake of sugar or intravenous infusion of glucose becomes imperative Patients afflicted with severe hyperinsulinism should always carry a tag with first-aid instructions

HYPERTHYROIDISM

The functional state of the thyroid gland *is governed* by the thyrotropic hormone of the pituitary. A primary exaggerated production of the *latter is* assumed to be responsible for some forms of hyper*thyroidism* Others are attributed to derangements of *cerebral* centers (emotional, encephalitic, carbon monoxide poisoning) which *are likely to* overstimulate the formation of thyrotropic hormone by *the* pituitary, or to the presence of an adenoma of the thyroid gland *In certain* iodine-poor

It returns toward normal at term. Cardiac output, stroke volume, and velocity of blood flow are likewise increased. The maximal development of all these phenomena coincides with the peak of total corticoid production between the 200th and 240th days of gestation. It also coincides with the highest statistical incidence of *congestive heart failure* in women with preexisting cardiac disease. Labor is usually relatively well tolerated by such patients, although some succumb to *shock* and *pulmonary edema* shortly post-partum.

The treatment of congestive heart failure in pregnancy is essentially the same as that outside of pregnancy. Even surgical interventions, such as mitral commissurotomy, have been successfully performed in selected cases.

Pharmacodynamic studies (Assali et al.) concerning an exaggerated depressor effect of tetraethylammonium bromide (TEAB) suggest a shift toward sympathetic neurogenic mechanisms in the maintenance of normal blood-pressure levels in pregnancy.

The *pretoxemic and toxemic complications* of pregnancy, such as sodium retention, edema, albuminuria, arterial hypertension, and eclampsia in the third trimester, are being increasingly recognized as the result of an *excessive production of mineralocorticoids* (Venning et al.). There are some indications that a part of these corticoids originates in the placenta. An abnormal pressor responsiveness to catecholamines, like that produced by desoxycorticosterone acetate administration, develops as an early feature of pretoxemia from about the thirtieth week on. It can be utilized as a prognostic criterion (Raab et al.) and calls for prophylactic and therapeutic measures, such as salt restriction and antihypertensive drugs.

MENOPAUSE AND HYPOGONADISM

Cardiovascular disturbances connected with the premenopausal and menopausal state are multiple, irregular, and generally not serious. *Flushing of the skin* on upper chest, neck and face, lability of the blood pressure with a tendency toward an increase, palpitation; dizziness; tachycardia; acrocyanosis; and Raynaud's phenomenon are common *Precordial pain*, with or without radiation into the left arm but independent of exertion and usually prolonged, is not infrequent. It is sometimes associated with transient "hypoxic" changes in the electrocardiogram.

Moderate *ankle edema, exertional dyspnea* and *sighing respiration* must not be mistaken as evidence of congestive failure. They may be explained as due to temporary overactivity of the adrenal cortex and of cardiorespiratory reflexes.

Treatment with estrogens (possibly combined with small doses of testosterone) is usually sufficient to suppress the most annoying symptoms. Roentgen-ray irradiation of the pituitary and of the adrenal glands has also been recommended. Barbiturates and rauwolfia derivatives are indicated for emotional instability and the accompanying fluctuations of the blood pressure.

Castration of both males and females is often followed by similar neurovegetative cardiac and circulatory manifestations, like those seen in the menopausal syndrome. They usually respond well to the substitutive administration of sex hormones.

ACROMEGALY AND GIGANTISM

Acromegaly, caused by eosinophilic tumors of the anterior pituitary lobe in the adult, and gigantism, its closely related equivalent beginning before puberty, are due to overproduction of the pituitary growth hormone and are often accompanied by slight over- or underfunction of the thyroid, as well as by mild adrenocortical overactivity.

One cardiac abnormality which seems to be rather specific for acromegaly (but less so for gigantism) is *enlargement of the heart*. It may greatly exceed the simultaneous increase in size of the other organs, and reach enormous proportions (up to 1,300 Gm), whether the blood pressure is elevated or not *Congestive heart failure* usually develops at the average age of 42 years and terminates the patient's life in a high percentage of cases. *Arterial hypertension* is less frequently observed and displays a labile, sometimes paroxysmal, character. General arteriosclerosis, renal arteriolar sclerosis, and degenerative alterations of the heart muscle are commonly found at autopsy.

Therapy consists of *surgical removal of the tumor*. Implantation of radon seeds and roentgen-ray irradiation are also used occasionally.

vision of the white blood count in order to avoid a possible dangerous agranulocytosis. They must be used continuously for *18 months* or longer to provide a lasting curative effect. Radioiodine therapy is easier to complete in a few sessions but may cause *irreversible myxedema if the dosage* is too high. Like all antithyroid forms of therapy, it is apt to *provoke hypercholesterolemia*, a potential long-range hazard to the coronary circulation

Digitalis ordinarily proves useful in patients with a rapid ventricular rate, provided that it is caused by atrial fibrillation, and is used in frank *congestive failure*.

HYPOTHYROIDISM

States of thyroid hypofunction may be artificially induced by thyroidectomy or antithyroid medication. *Primary hypothyroidism* develops relatively frequently in middle-aged women and, as a secondary feature, in cases of *hypopituitarism (pituitary myxedema)*, especially *in multiparous women* The incidence of hypothyroidism in men is one-tenth to one-fifth that prevalent among women. In cases of sporadic or endemic *cretinism*, a hypofunction of the thyroid appears as a side phenomenon in combination with severe primary cerebral deficiencies

The term *myxedema* refers to the accumulation of a protein-rich gelatinous *material in the subcutaneous tissues*. It must not be confused with the true "pitting" edema of congestive heart failure. It is associated with a puffy, pasty appearance of the dry, scaly skin, coarse, brittle hair; *constipation, oversensitivity* to cold temperatures; general fatigue; a hoarse, husky voice; *slow*, poorly articulated speech; and marked *mental apathy*.

Except in cases of "pituitary myxedema," the *blood cholesterol level is elevated*. Protein-bound iodine of the *serum is reduced*, and the uptake of radioiodine *by the thyroid gland* is diminished or entirely absent. A markedly *lowered basal metabolic rate* is consistent with the diagnosis of hypothyroidism, but moderate depressions (as much as −25 per cent) *may* also occur, unrelated *to thyroid underfunction* (Kurland et al.). The blood pressure level is *not characteristically affected* by the hypothyroid state The pulse pressure may be diminished Catecholamine activity is reduced to a minimum and, accordingly, heart action and peripheral blood flow are sluggish; the cardiac output is decreased A *low voltage of P, T, and QRS* represents the most specific electrocardiographic *feature of the "myxedema heart."* It is believed to be caused by short-circuiting and dissipation of the action currents within the swelled myocardium itself and within the other *myxedematous tissues* that connect the heart with the *registering electrodes*. Depression of the voltage becomes maximal in the presence of pericardial effusion. The latter *consists of fluid with a high* protein content. In many instances, it is responsible for an *enlargement of the heart silhouette* on roentgenography. This enlargement disappears *after the pericardial sac is tapped* (Fig 16-9).

Fig 16-9. Enlargement of the cardiac silhouette in myxedema caused by pericardial effusion Tapping of the pericardial sac reveals the true size of the heart (From Zdansky Roentgendiagnostik des Herzens und der grossen Gefasse, 1949.)

areas of the world (e.g., the European Alps), thyrotoxicosis due to excessive medicinal intake of inorganic iodine compounds or thyroid preparations, is widespread.

The *diagnosis* of hyperthyroidism rests upon (1) a well-known but variable clinical picture (diffuse or nodular enlargement of the thyroid gland, wide palpebral aperture without or with exophthalmos, moist flushed skin, dermographism, silky hair, fine tremors, psychomotor restlessness, loss of weight, oversensitivity to warm temperature); and (2) laboratory tests (evidence of increased basal metabolic rate and protein-bound iodine and a greater radioiodine uptake by the thyroid gland). The incidence of thyrotoxicosis is far greater in women than in men

The *cardiovascular manifestations* of hyperthyroidism are based upon an intensive potentiation of epinephrine and norepinephrine. Accordingly, they mimic the effects of these neurohormones cardiac acceleration, palpitation; increased stroke volume, cardiac output, and pulse pressure, augmented pulse-wave velocity; and increased peripheral blood flow There is a theory proposing that these phenomena take place "in order" to fulfill the oxygen demands of the peripheral tissues; however, this ignores the catecholamine-mediated influence of the thyroid hormone on the myocardium, a phenomenon which can be observed even on isolated hearts.

Paroxysmal and ultimately permanent *atrial fibrillation* occurs in untreated patients, especially in the more advanced age groups. This phenomenon, as well as an occasionally observed bradycardia, prolongation of the P-R interval, and an only moderate rise of myocardial oxygen uptake (Leight et al) suggests a simultaneous accentuation of cholinergic mechanisms

Preexisting "organic" heart disease is often greatly aggravated by thyrotoxicosis

Interesting analogies exist between the thyrotoxic and the beriberi heart, both of which are characterized by exaggerated catecholamine action: the former due to abnormal functional potentiation, the latter due to actual accumulation of catecholamines in the heart muscle. A relative thiamine deficiency is also believed to participate in the thyrotoxic cardiovascular syndrome.

Although the systolic blood pressure is sometimes moderately elevated in hyperthyroid patients, the diastolic pressure tends rather to fall (epinephrine effect). The frequently heard statement that thyrotoxicosis promotes essential hypertension is unfounded. A *slight enlargement of the heart silhouette* is sometimes noted on roentgenography and an unusual prominence of the conus of the right ventricle represents a characteristic peculiarity of the thyrotoxic heart. At autopsy, the heart muscle is often found to be hypertrophied, with disseminated degenerative and necrotic foci, similar to those experimentally produced by epinephrine.

Coronary atherosclerosis and myocardial infarctions are comparatively uncommon (Jeffers et al.), probably because of the anticholesterolemic effect of the thyroid hormone Accordingly, precordial pain does not occur as frequently as one might expect in view of the effects of the thyroid hormone in promoting precordial pain in patients with coronary sclerosis.

The electrocardiographic signs are nonspecific, except for the frequent occurrence of *high P and T waves*, which have been interpreted as a manifestation of exaggerated sympathetic tone. Depressions of S-T and T make their appearance in more advanced stages when myocardial hypoxia and degeneration become prominent.

The three main forms of *treatment* for hyperthyroidism and for its cardiac complications are· thyroidectomy; use of antithyroid drugs, such as propyl- and methylthiouracil or Tapazole; administration of radioactive iodine

Surgery has been partially replaced by the medical procedures, but it still remains the treatment of choice in most adenomatous cases as the best guarantee against later malignancy and in the presence of tracheal compression Iodine, alone or in combination with propylthiouracil, is used in the preoperative period to improve the patient's condition rapidly and to decrease the surgical risk. Atrial fibrillation may appear and persist for several days following thyroidectomy. The so-called "thyrotoxic crises," which are in rare instances elicited by the surgical trauma or by other stressful situations, are probably attributable to a secondary acute adrenocortical insufficiency and are to be treated accordingly.

Thiourea derivatives require constant super-

sudden death, especially among children with tetany, have been ascribed to an increased sensitivity of the cardiovascular system to epinephrine.

Therapy consists essentially of attempts to restore a normal blood calcium level by administration of parathyroid hormone, calcium gluconate, or dihydrotachysterol.

CIRCULATION TIME IN HYPERTHYROIDISM

Blumgart et al. (1931), with the aid of radium C, and Tarr et al., by the use of Decholin, have demonstrated that in hyperthyroidism there is a heightened velocity of blood flow and an abbreviated circulation time which are inversely proportional to the level of the basal metabolism

In hyperthyroidism uncomplicated by coexisting valvular or myocardial disease or by atrial fibrillation, the velocity of blood flow may be remarkably increased, varying with the level of the metabolism. The circulation times of both segments of the pulmonary pathway from the antecubital vein to the pulmonary capillaries ("arm-to-lung" time) and from the pulmonary capillaries to the capillaries of the tongue ("lung-to-tongue" time) are proportionately decreased. Thus, the "arm-to-lung" time with ether (Hitzig) may be within the range of from 3 to 4 sec, whereas the "arm-to-tongue" time with Decholin or saccharin or calcium may be reduced to levels of 7 to 10 sec in contrast to a normal value of 10 to 16 sec with the same methods

The augmented circulation time in hyperthyroidism increases about 30 to 70 per cent in order to balance an increased cardiac output, an increased venous return, and a slightly increased circulating blood volume. The increased circulation speed is a reflex response to the increased oxygen consumption of a heightened metabolism which compels increased demands of the tissues for more oxygen per unit of time This disturbance in the oxidative needs of the tissues leads to an accumulation of metabolites which causes reflex lowering of the peripheral resistance through the mechanism of vasodilatation and short-circuiting effects of newly opened and functioning arteriovenous shunts.

When hyperthyroidism complicated by coexisting heart disease ushers in congestive failure as a consequence of either atrial fibrillation or myocardial strain (both pathogenetically related to thyrotoxicosis), the circulation time may remain rapid or drop within normal limits depending upon the level of the metabolism and the degree of heart failure. Even in cases with a high initial *venous pressure* and a marked hepatojugular *reflux (characteristic* of congestive failure), *the circulation time* may still remain within the normal healthy range of from 10 to 16 sec or slightly higher (Hitzig). *The syndrome of congestive heart failure with a normal or* rapid circulation time (if anemia, beriberi heart, fever, acute pulmonary *insufficiency*, or arteriovenous fistula can be excluded) is pathognomonic of hyperthyroid*ism complicating* coexisting heart disease

HYPERTHYROIDISM VERSUS NEUROCIRCULATORY ASTHENIA

Circulation times offer a simple bedside tool for the clinician who is at times confronted with the problem of differentiating between hyperthyroidism and conditions which mimic it closely. The latter includes neurocirculatory asthenia and various forms of anxiety states, in which tachycardia is a prominent presenting symptom. Because of the hypermetabolism of Graves' disease, the cardiac output is *increased*. While the circulation time remains within *the normal* range in neurocirculatory asthenia, it is *frequently* abbreviated in hyperthyroidism, the "arm-to-tongue" time often being reduced to a range of 6 to 9 sec

THE FATTY HEART

Two types of fatty change occur in the heart (1) fatty degeneration and (2) fatty infiltration Fatty degeneration *is part of* a degenerative process, and the consensus is that it has *nothing in* common with "fatty heart." Fatty infiltration of *the myocardium*, lipomatosis cordis, or cor adiposum, *are* terms often used instead of "fatty heart"

Both the pseudoenlargement of the heart and the pseudoedema of the peripheral tissues in hypothyroidism have created considerable confusion as to whether *congestive failure* is a characteristic feature in myxedema. Absence of true congestive phenomena, unresponsiveness to digitalis, and improvement under thyroid medication, set the picture of "the myxedema heart," apart from that of congestive failure. It must be emphasized, however, that hypothyroidism may be associated with congestive heart failure in certain circumstances.

Severe *coronary atherosclerosis* is a common complication of hypothyroidism, presumably in connection with its concomitant high cholesterol levels. The not infrequent occurrence of *precordial pain* and *signs of congestion* can be explained on this basis. Accordingly, the usefulness of therapeutic thyroid depression in cases of angina pectoris and congestive failure with coronary sclerosis is limited, and the loss of thyroid function may ultimately aggravate such cases.

At autopsy, the hearts of persons who have died in untreated hypothyroidism appear pale, flabby, and sometimes dilated If an increase in the ventricular mass is seen, this is due to myxedematous swelling of the myocardial fibers rather than to hypertrophy As a result of the common presence of coronary atherosclerosis, fibrotic changes are often noted.

The specific *treatment* for hypothyroidism consists of the administration of *thyroid hormone* (U.S P dry powder preparations) or of the more rapidly acting *triiodothyronine* (Zondek et al). Since patients with "pituitary myxedema" are extremely sensitive to the stress-producing effects of thyroid medication and may succumb to it in a state of hypoadrenocortical crisis, it is mandatory to administer the thyroid hormone to such patients only in minimal doses, and to combine it with *cortisone, ACTH, or both* Thyrotropic hormone of the anterior pituitary may be used instead of thyroid preparations (De Gennes).

Great caution is necessary in patients over fifty and in those with a history of coronary or hypertensive heart disease Severe precordial pain or heart failure may be precipitated by thyroid preparations through their potentiation of catecholamines It is preferable to increase the medication slowly over several months until a maintenance dosage is obtained, rather than to take risks through hasty overtreatment. Morphine and barbiturates are contraindicated in hypothyroid patients.

HYPERPARATHYROIDISM

The result of excessive hormone production by adenomas of the parathyroid glands is revealed in disturbances in the metabolism of calcium and phosphorus. Calcium is mobilized from the bones, thus giving rise to widespread decalcification of the skeleton, partly in cyst-shaped areas, and especially in the long bones. Some of the calcium is eliminated with the urine, while excess amounts accumulate as kidney and urinary stones or are absorbed by soft tissues, including the vascular walls and the myocardium. The diagnosis is based on the typical radiological findings, a high level of ionized calcium and of alkaline phosphatase, and a low concentration of inorganic phosphorus in the blood. *Abbreviation of the electrical systole, with a shorter Q-T interval,* is frequently seen in such cases. Renal lesions may contribute to the development of nephrogenic arterial hypertension. Caution in the use of digitalis glycosides has been recommended in view of a possible exaggeration of digitalis toxicity by the hypercalcemia.

HYPOPARATHYROIDISM

This condition affects the metabolism of calcium and phosphorus in a sense opposite to that prevailing in hyperparathyroidism. It lowers the level of ionized calcium in the blood and usually reverses the calcium/phosphorus ratio It occurs following spontaneous lesions of the parathyroid glands, after surgical removal of an adenoma or of normal parathyroids in connection with thyroidectomy, or during lactation (unusually large amounts of calcium are eliminated with the milk).

Tetanic spasms of the striated muscles, particularly of the extremities, and of some smooth muscular structures, trophic changes of teeth and fingernails, and perinuclear cataracts, are the most conspicuous clinical phenomena of hypoparathyroidism.

In keeping with the low calcium concentration of the blood, *the electrocardiographic Q-T interval is usually prolonged.* Occasional episodes of precordial pain and instances of

Saphir and Corrigan state that "fatty heart" used to be diagnosed frequently by pathologists and clinicians but that the diagnosis has been rare in recent years They quoted Corvisart (1818) as admitting the existence of the entity, but he had not observed it personally and had cited three cases in the literature. White stated that the truth probably lies between the two extreme views that "fatty heart" is common and dangerous or that it does not exist at all as a clinical entity.

PROGNOSIS

Saphir and Corrigan, correlating the clinical findings in 58 autopsied cases, divided the patients into three groups: (1) those in whom *fatty infiltration* was the only cause of death, (2) those in whom it was a contributing factor, and (3) those in whom it was an incidental finding There were two patients in group 1, one of whom died suddenly, 29 patients in group 2 who died of pulmonary emboli, pneumonia, or other disease which could have been tolerated had the heart been normal; and 25 patients in group 3 They mention that fatty infiltration may cause sudden death without premonitory symptoms.

Although the prognosis in obesity is not poor, it is well known that obesity increases operative risk, that mortality rates increase in obesity, and that death rates following trauma are higher in obese patients The part played by the fatty heart is not known.

THERAPY

A sensible program of weight reduction is of prime importance prophylactically and therapeutically. Usual therapeutic measures for myocardial failure should be carried out as necessary.

Obese patients should avoid undue physical strain.

CAUSATIVE FACTORS

Saphir and Corrigan state that general obesity is associated with increased subepicardial fat and the extension of it, and that alcoholic drinks such as malt liquors and sweet wines favor its occurrence. In 136 autopsies on obese subjects, fatty infiltration was found in all (Smith and Willius). White (1951) states that there is a greater tendency to fatty infiltration in obese individuals but that the association of cor adiposum with general obesity is doubtful because of many exceptions: fatty heart occurs in the absence of obesity and obesity is found without fatty heart. Obesity itself puts an added strain on the heart by (1) increasing the body weight, (2) increasing body surface, which requires a tremendous extension of the vascular tree, and (3) increasing the total body metabolism (Willius).

PATHOGENESIS AND PATHOLOGIC CHANGES

In fatty infiltration, fat is grossly deposited in abundance in the subepicardium, infiltrates the myocardium, and replaces some of the myocardial fibers. During routine autopsies, Saphir and Corrigan found a large number of hearts infiltrated with fat, 58 of these were examined closely. The hearts weighed 200 to 800 Gm, mostly 300 to 400 Gm The site of the most extensive involvement was the right ventricle. Fat seemed to follow the course of the coronary arteries along the perivascular spaces and to infiltrate the myocardium The severity varied from moderate infiltration, involving only the outer myocardial layers, to replacement of the entire right ventricular wall In a few instances, subendocardial layers of the left ventricle were involved Microscopically, myocardial changes varied from atrophy to complete replacement of muscle fibers In severe lesions, there were islands of fat discontinuous from the subepicardial fat Preservation of blood vessels was noticeable, and inflammation was absent

Smith and Willius emphasized the fact that excessive amounts of fat were not deposited within the cells as is the case in fatty degeneration.

CLINICAL DESCRIPTION

Heart disease may or may not be present in obesity, and usually there is little or no clinical evidence of it. There may be slight to moderate *dyspnea*, a little *cardiac enlargement*, a little feebleness of the heart sounds, slight reduction in strength of the apical impulse and (rarely) evidence of congestive failure In a clinicopathological conference, P D. White (1954) discussed an obese patient who died after an episode of precordial pain and collapse; no cause of death could be found at necropsy except extensive fatty infiltration of the heart.

Of 136 cases reported by Smith and Willius, heart disease was not evident clinically in 38 per cent, and varying degrees of heart failure were present in 7 per cent which showed no pathological change other than fatty deposition and fatty infiltration of the heart. The remainder had symptoms of heart disease from other causes

Obese individuals often have some exertional dyspnea or the effort syndrome because of the lack of exercise and their excess weight.

TECHNICAL STUDIES

Roentgenographic examination may show some cardiac enlargement, but there are two sources of error in estimating heart size. In stout, obese persons, the diaphragm tends to be high and the heart horizontal; under such conditions the heart appears larger than normal in transverse diameter and area. When the transverse cardiac diameter of a transverse heart approaches the long diameter in measurement, 1 or 2 cm should be subtracted from the transverse diameter, and about 25 cm from the area, in calculating the heart size (White) The other source of error is the presence of a triangular fat pad at the left and, occasionally, the right pericardiodiaphragmatic angles

The *electrocardiogram* in the fatal case discussed by White showed inverted T waves in leads V_1 through V_5 and in lead III, low T waves in leads I, II, aVF and V_6; and R and R′ waves in leads V_1 and V_2

DIAGNOSIS

There is a question about the clinical diagnosis in any case, and fatty heart should only be diagnosed pathologically in the absence of other causes of death. Fatty heart can only be suspected clinically in obese individuals with enlarged hearts or in instances of congestive failure without apparent cause.

case reports, a study by Goodhart and Jolliffe of 83 alcoholics deserves mention· 80 per cent of these showed signs of dietary deficiency, and about one-third had electrocardiographic abnormalities. Dramatic improvement following thiamine therapy is recorded in several reports (Jones et al). Weiss and Wilkins (1937a) observed cardiac changes similar to those of beriberi in a survey of 120 patients with nutritional deficiency. Weiss (1940) concluded that beriberi with cardiovascular manifestations existed in America and Europe. He attributed these manifestations primarily to thiamine deficiency Blankenhorn presented 37 cases of *beriberi heart disease* and described the diagnostic criteria and necropsy findings

Heart disease in the post-partum period closely resembles the disease in alcoholics

the cardiac pathology found in women dying in the puerperium Blacker (1907) and Campbell (1923) pointed out the occurrence of nonvalvular heart disease in the puerperium. Hermann and King (1930) described four cases of myocardial failure of uncertain origin in the puerperium. Williams (1933) stated that 1.5 per cent of cardiac deaths during and soon after pregnancy were the result of "idiopathic" disease Gouley et al. (1937) made a clinical study of seven patients with cardiac decompensation in the puerperium and included autopsy findings in some of them The degenerative changes in the myocardium were emphasized in most reports The clinical findings in 27 patients with post-partum heart disease were described by Hull and Hafkesbring (1937). Sodeman (1940) described two types of failing hearts in the post-partum period; the nephritic and the nonnephritic type. Because

factor Grossly deficient diets were described in a number of the other reports, and attention was drawn to the similarity between the clinical features of cardiac beriberi and post-partum heart disease. The usual manifestations consisted of dyspnea, cardiac dilatation, an accentuated 2d pulmonary sound, gallop rhythm, peripheral edema, and electrocardiographic changes Vilter and McKee (1943) and Mackinon and Mackeen (1949) described further cases of post-partum heart disease. Necropsy revealed degenerative changes in the myocardium. Woolford (1952) described similar cases. Meadows (1957) documented cases from general hospitals

CARDIAC MORPHOLOGY

The following description of the cardiac morphology in post-partum heart disease and heart disease in alcoholics is based on observations in patients at the Cook County Hospital *Both ventricles are hypertrophied and dilated and usually contain adherent and partially organized thrombi* (Figs. 16-10 and 16-11A) *which may give rise to embolic phenomena* Dilatation of the outflow tract of the right ventricle or predominance of right heart involvement, as seen in oriental beriberi, is not a feature. Endocardial fibrosis, if present, is not conspicuous and is then restricted to areas underlying mural thrombi. Microscopically, cellular foci of inflammation are lacking The myocardial fibers exhibit varying degrees of

Fig. 16-10. A Marked dilatation and hypertrophy of the right ventricle with hypertrophy and flattening of the papillary muscle; valves are not involved. Arrow shows mural thrombi B Hypertrophied and dilated left ventricle with mural thrombi between the trabeculae carneae.

PATHOLOGICAL ASPECTS

The cardiac form of *oriental beriberi*, as described by Aalsmeer and Wenckebach, represents a well-defined clinical and pathological entity Its manifestations are generally recognized to be the result of *vitamin B_1 deficiency*. Other forms of nutritional heart disease have been described in Africa, and they have been provoked in experimental animals The disease encountered in the Bantu differs from oriental beriberi in a number of important clinical and pathological aspects, and has been reported to respond to a well-balanced diet while being refractory to thiamine therapy In the conditions mentioned, impressive clinical and gross pathological features are reflected histopathologically in distinctive, though not specific, regressive changes of the myocardium.

In the large general hospitals of the United States, heart disease is observed which is characterized by *intractable cardiac failure* clinically, and dilatation of the heart chambers with *mural thrombus* formation pathologically. The causative factors usually responsible for such conditions are lacking. Since the disease occurs in *alcoholics* and in women *following the puerperium*, it has been associated with these circumstances, though as yet with insufficient evidence. Similar lesions have been observed in other parts of the western world, e g, Great Britain, France, and Germany They are presented here as a unit with the full realization that they are characterized by the absence rather than the presence of a distinctive set of causative factors.

HISTORICAL BACKGROUND

Cardiac disease in alcoholics or in persons with malnutrition has been recognized for many years Graham Steell (1906) alluded to the cardiac failure of beer drinkers Magniel described cases of heart disease found in association with excessive alcohol intake, manifested by enlarged hearts, gallop rhythm, obesity, and polyneuritis. Of numerous further

[1] Because there are several still incompletely known aspects of these clinical syndromes, four separate contributors will discuss them with some degree of overlapping. *Editor.*

of the heart has been regarded as consistent with beriberi heart disease. The difficulty in reproducing the pathologic lesions of human beriberi in experimental animals (Weiss et al., 1938, Ashburn et al; Wintrobe) does not help to clarify the variations of beriberi heart disease. Failure of beriberi patients to respond to thiamine therapy may conceivably be due to irreversible cardiac changes, perhaps through progression to fibrosis, but this is hard to prove in the individual case, and a cautious attitude toward the diagnosis of beriberi heart disease would seem in order. The designation of *nutritional heart disease* seems preferable in most cases, since a nutritional factor other than vitamin B_1 may be involved. Support for this view is derived from the similarity of many cases to those in the South African Bantu. It must be realized that causes other than malnutrition may produce similar morphologic changes, and in alcoholics, particularly, the toxic effects of alcohol or other toxins must be considered. Since the changes described can be caused by malnutrition, consideration of this origin seems justified in patients who present an obscure picture of cardiac pathology and have a poor nutritional background.

FURTHER PATHOLOGICAL ASPECTS

The response of the heart to injury, regardless of cause, is identical in many instances, owing to the limited capacity of the cardiac structures to react to noxious agents. Degeneration, necrosis of myofibrils, exudative or productive inflammation, and proliferation of fibroblastic tissue are the most common nonspecific responses to injury. It is therefore apparent that, in the absence of an associated lesion regarded as pathognomonic, any attempt to investigate in individual cases the nature of the structural disorder will unavoidably lead into the field of speculation.

The limit of our ability to present etiological diagnosis by a merely morphologic method is clearly reflected by the increasing number of reports which, for obscurity of cause, are placed in the category of the so-called "idiopathic carditis." Myocardial disease which cannot be ascribed to any of the ascertained causes forms an important cardiological problem. Obscurity of cause is not a justification for grouping together obviously heterogeneous conditions, and any effort to link the history of a failing heart to the anatomical observation through the possible causative agent is a step in the proper direction. It is known that the heart is vulnerable to deprivation and that nutrients are particularly necessary to the functional and anatomical integrity of the cardiac structures.

The weight of the heart is decreased in starvation. A diminution in weight of 20 to 30 per cent of normal was found in [illegible]

These data parallel closely those obtained in rats subjected to complete starvation while water was still administered.

The diminution in weight of the organ is mostly due to thinning of the myocardium, which often shows a brownish discoloration, the so-called *brown atrophy*. The subepicardial fat is also reduced in amount and the reduction is usually accompanied by an infiltration of fluid, this results in a gelatinous appearance of the fatty deposits, generally known as *serous atrophy*. The microscopic counterpart is a reduction in the size of the muscle fibers with occasional loss of striations, vacuolization, and fatty degeneration. An accumulation of yellowish-brown granular pigment, largely hemofuscin, is frequently noticeable in the sarcoplasm, usually at the nuclear poles. Hemosiderin granules in proximity to myofibrils have been noted by the author in mice, rats, and rabbits after 5 to 13 days of complete starvation. There was associated atrophy, fragmentation, or hyaline degeneration of myofibrils, and the supporting collagenous framework was condensed in the areas of greater damage. Foci of round-cell infiltration were noticed in some instances between myofibrils, around the walls of blood channels, and beneath the mural endocardium. Since iron is present in cardiac myohemoglobin, it was assumed that the free hemosiderin granules had resulted from lysis of myofibrils.

Follis (1948) has made clear the distinction between "specific" and "nonspecific" alterations resulting from dietary restriction. If all

Fig. 16-11. A. Myocardium with relatively recent thrombus Hematoxylin-eosin. ×85. B. Myocardial fibers showing inter- and intracellular edema. Hematoxylin-eosin. ×260.

degenerative change and, usually, marked *intra- and extracellular edema* (Fig. 16-11B). Lipofuscin pigment around the nuclear poles is commonly seen Occasional foci of fine fibrosis may be present, but the coronary arteries are normal. In general, the patients are in *low-output failure* and present a low pulse pressure, electrocardiographic changes, and gallop rhythm, they do not respond to the usual cardiac regime. The historical and morphologic evidence of malnutrition often includes a poor diet, alcoholism, serum protein changes, the presence of myocardial lipofuscin, loss of basophilia of the pancreatic acinar cells, and failure of the liver to neutralize estrogens, as evidenced by gynecomastia, testicular atrophy, prostatic squamous metaplasia, and pituitary basophilism.

RELATION TO OTHER TYPES OF HEART DISEASE

What is the relationship of these cases to other groups of nutritional cardiopathies? From Africa have come descriptions of two major groups of heart disease. The first, called *endomyocardial fibrosis*, occurs mainly in Southern Uganda and in the Sudan (Davies) (See Chap. 12.) The outstanding pathological feature of this disease is endocardial fibrosis It involves the apical portions of the ventricles and extends into the atrioventricular valves, often rendering them incompetent. The ventricular surface of thickened endocardium is often continuous with blood clot while the deeper layers blend in with fibrotic myocardium. The initial damage is thought to develop in the subendocardial myocardium with subsequent mural thrombus formation and organization. The characteristic localization of the lesion with involvement of the mitral and tricuspid valves, the scarcity of embolic phenomena, and the obscure origin make this condition a distinct one. A similar picture, called *diffuse endomyocardial sclerosis*, has been reported from Europe (Mumme; Lynch), and the United States (Smith et al; McNichol et al.); and there has been some evidence for a nutritional origin The second group from Africa was reported in the Bantu (Becker, Higginson et al.). In these patients, the hearts are enlarged, the ventricles contain mural thrombi near the apex, and the valves are not involved. Endomyocardial fibrosis is not prominent, and embolic phenomena are common Since the Bantu patients with heart disease had liver lesions (presumably due to malnutrition), responded to a dietary regime, and relapsed when put back on their accustomed diet, a good case can be made out for a nutritional origin of this condition The cardiac morphology of alcoholic or post-partum heart disease resembles that described in the Bantu in many ways, but differs from endomyocardial fibrosis.

The distinctive features of *oriental beriberi* are (1) the predominant involvement of the right heart, associated with a prominent pulmonary conus, and (2) its response to thiamine therapy In the later presentations of *occidental beriberi heart disease*, some authors describe a well-defined clinical picture with a good response to thiamine, while others use wider diagnostic criteria and report no therapeutic effect of thiamine. The morbid anatomical features seem no more definite, and involvement of either the right side or both sides

cardium became involved and the degenerative changes were seen to be followed first by leucocytic infiltration and then by fibroblastic proliferation Scarring became apparent around the 87th day, and in rats carried on a low-potassium regime for as long as 327 days, healed lesions were seen side by side with fresh alterations Comparable myocardial changes have been described in dogs, mice, and cattle It has been shown that the reticulin network supporting the myofibrils escapes injury. This may find explanation in the very low potassium content of the connective tissue, almost identical with that of extracellular fluid. The survival of the endothelium lining the mural and valvular endocardium and of the basement menbranes of the blood capillaries, even in the midst of necrotic foci, may also be explained on the basis of the low potassium requirement of these particular structures.

In potassium deficiency, strain is an aggravating factor, on the other hand, rubidium and, to a lesser degree, cesium seem to have a protective effect against the changes of hypokalemia. A protective effect of boron (as boric acid or borax) has not been confirmed Likewise poorly understood is the mechanism of the protective effect of a thiamine deficiency in the hypokalemic rat.

Myocardial lesions similar to those induced by a potassium-deficient diet have been described in rats treated with desoxycorticosterone. Furthermore, when potassium-deficient animals are treated with a cortical hormone, myocardial changes occur sooner and are more extensive than when either one or the other treatment is employed alone. Selye and Pentz suggested that the desoxycorticosterone-produced myocardial lesions resemble those of rheumatic fever, but this identity has not been accepted

Experimental diets deficient in sodium, chlorine, phosphorus, manganese, zinc, and calcium have failed to produce morphological changes in the heart muscle of rats.

Blaxter et al noticed focal myocardial necrosis, hemorrhage, and thrombosis in magnesium-deficient calves. So far, these are the only observations that offer a *morphologic basis* for the disturbances in cardiac function that occur in magnesium deficiency

Bennetts et al found atrophy of myofibrils and replacement fibrosis in cattle grazing in copper-deficient pastures, while Schultze noticed a decrease in the cytochrome activity of heart muscle in rats placed on a low copper regime

Iron is present in cardiac myohemoglobin. Although it is well known that cardiac changes occur in association with anemia, so far myocardial changes have not been found in iron-deficient animals (Follis, 1956).

VITAMINS

The term *vitamin* is usually applied to a number of organic substances, soluble in fat or water, which are needed in minute quantities to maintain the metabolic integrity of the cells. By *vitamer* is meant a structurally related substance having similar biological activity

There is no indication that a *vitamin A deficiency* has any effect on the heart of growing or adult animals. However, Wilson and Warkany observing rats born of mothers fed vitamin A–deficient rations prior to and during gestation, noted an appreciable number of cardiovascular anomalies including structural disorders of the myocardium. Another example of the profound effect which deficiency of a single nutrient at a critical period of growth may have on the development of an organ system is the frequent development of interventricular septal defects, and of abnormalities in the aortic arch derivatives, in the young of rats kept, during gestation, on a diet deficient in pteroylglutamic acid Similar cardiovascular anomalies have been observed in the offspring of rats fed galactoflavin (a riboflavin antimetabolite) during gestation (Baird et al).

It is well established that the cardiac musculature shares with the skeletal muscle the greatest impact of alpha-tocopherol deficiency. Myocardial changes have been demonstrated in rats, rabbits, and calves. Necrosis, loss of striations of myofibrils, nuclear pyknosis, and karyorrhexis, followed by inflammatory reaction and then by fibroblastic proliferation and scarring, is the sequence of changes most frequently encountered. Calcification of fibers has been described in some instances The accumulation in myofibrils of ceroid before necrosis takes place, and the presence of *acid-fast*

Comparable disseminated *myocardial lesions*

the essential nutrients (amino acids, vitamins, and fatty acids) are withdrawn from the diet or are utilized in insufficient quantities, the ensuing changes reflect the general disorder of inanition (*athrepsia*) and are "nonspecific" with respect to a particular deficiency. In the absence from the diet of one or more essential nutrients or in faulty utilization of this or that particular nutrient, "specific" tissue alterations take place. However, this does not mean pathognomonic in a morphologic sense.

The advent of purified rations and crystalline vitamins has opened a new alley in the investigation of the effects of selected dietary deficiencies. Spontaneous diseases secondary to certain dietary deficiencies occur in man, but preceding, associated, interdependent, or intercurrent disorders from other causes often make difficult the evaluation of the physiological and morphological changes which are directly due to the dietary deficiency. It is therefore not surprising that most of our knowledge of "specific" nutritional disturbances is based on the results of observations in the experimental animal, in which controlled conditions are more easily achieved.

When the concentration of a particular nutrient in the tissues of the heart falls to a critical level, a metabolic derangement takes place which reveals itself by various degrees and types of disturbance. This disturbance can manifest itself by alterations in function, appearance of abnormal metabolites in blood or excreta, or morphological deviations from the normal. The latter may be so pronounced as to be detected by the naked eye, or may be of microscopic or submicroscopic dimensions. Recent advances in the field of histochemistry have made it possible to demonstrate directly particular nutrients, such as riboflavin or vitamin A, within the cells in tissue sections.

The above course of events does not take place in every instance and a sequence is not always demonstrable. The deficient state can be so severe and abrupt as to induce an overwhelming functional disorder which is incompatible with life, and in this case morphological changes may be slight or even absent, or the deficiency may be of longer duration, but less severe in degree, and in this case structural alterations take place This is well exemplified by Follis' observations (1943) on the response of the swine heart to acute or chronic thiamine deficiency. In the acute experiment the animal dies, ostensibly of heart failure, with virtually no myocardial structural change; on the other hand, in the animal which withstands a lesser degree of dietary deficiency for a longer time, myocardial alterations become visible.

Of the 96 elements which are now known, seventeen or eighteen are indispensable to the maintenance of normal cardiac metabolism and structure.

AMINO ACIDS

Amino acids are generally classified as *non-essential:* those which can be synthesized by the organism; and *essential:* those which must be furnished preformed in the diet Available information indicates that upon withdrawal from the diet of all of the essential amino acids, no striking myocardial alterations, either in function or in structure, take place.

INORGANIC ELEMENTS

Since the classic observations of Ringer, the importance of potassium in the normal functioning of the heart has been well recognized. The term "hypokalemic myocarditis" has been proposed to indicate the lesion occurring in patients with potassium deficiency, and the condition is now listed in the Cardiovascular Registry of the Armed Forces Institute of Pathology. The lesion consists mainly of focal myocardial necrosis followed first by macrophagic and lymphocytic reaction, and in later stages by fibroblastic proliferation and scarring. Myocardial alterations interpreted as hypokalemic have been described in Cushing's syndrome, in desoxycorticosterone treatment, and in certain types of chronic nephritis; in one instance fresh necrosis has been shown in Addison's disease. It is not clear whether potassium deficiency alone or its combination with some other metabolic disturbance is responsible for these changes.

Experimentally, Follis et al. (1942) have traced the sequence of changes that occur in the rat's heart after the rat is placed on a diet deficient in potassium. Below a critical potassium level, alterations were noticed as early as the eighth day. These changes were focal in distribution and consisted mainly of loss of striations, lysis, and necrosis of myofibrils As the deficiency progressed, larger portions of myo-

cardium became involved and the degenerative changes were seen to be followed first by leucocytic infiltration and then by fibroblastic proliferation. Scarring became apparent around the 87th day, and in rats carried on a low-potassium regime for as long as 327 days, healed lesions were seen side by side with fresh alterations Comparable myocardial changes have been described in dogs, mice, and cattle. It has been shown that the reticulin network supporting the myofibrils escapes injury. This may find explanation in the very low potassium content of the connective tissue, almost identical with that of extracellular fluid. The survival of the endothelium lining the mural and valvular endocardium and of the basement menbranes of the blood capillaries, even in the midst of necrotic foci, may also be explained on the basis of the low potassium requirement of these particular structures.

In potassium deficiency, strain is an aggravating factor; on the other hand, rubidium and, to a lesser degree, cesium seem to have a protective effect against the changes of hypokalemia A protective effect of boron (as boric acid or borax) has not been confirmed Likewise poorly understood is the mechanism of the protective effect of a thiamine deficiency in the hypokalemic rat.

Myocardial lesions similar to those induced by a potassium-deficient diet have been described in rats treated with desoxycorticosterone Furthermore, when potassium-deficient animals are treated with a cortical hormone, myocardial changes occur sooner and are more extensive than when either one or the other treatment is employed alone Selye and Pentz suggested that the desoxycorticosterone-produced myocardial lesions resemble those of rheumatic fever, but this identity has not been accepted.

Experimental diets deficient in sodium, chlorine, phosphorus, manganese, zinc, and calcium have failed to produce morphological changes in the heart muscle of rats.

Blaxter et al. noticed focal myocardial necrosis, hemorrhage, and thrombosis in magnesium-deficient calves So far, these are the only observations that offer a morphologic basis for the disturbances in cardiac function that occur in magnesium deficiency.

Bennetts et al. found atrophy of myofibrils and replacement fibrosis in cattle grazing in copper-deficient pastures, while Schultze noticed a decrease in the cytochrome activity of heart muscle in rats placed on a low copper regime.

Iron is present in cardiac myohemoglobin. Although it is well known that cardiac changes occur in association with anemia, so far myocardial changes have not been found in iron-deficient animals (Follis, 1956).

VITAMINS

The term *vitamin* is usually applied to a number of organic substances, soluble in fat or water, which are needed in minute quantities to maintain the metabolic integrity of the cells. By *vitamer* is meant a structurally related substance having similar biological activity.

There is no indication that a *vitamin A deficiency* has any effect on the heart of growing or adult animals. However, Wilson and Warkany observing rats born of mothers fed vitamin A–deficient rations prior to and during gestation, noted an appreciable number of cardiovascular anomalies including structural disorders of the myocardium Another example of the profound effect which deficiency of a single nutrient at a critical period of growth may have on the development of an organ system is the frequent development of interventricular septal defects, and of abnormalities in the aortic arch derivatives, in the young of rats kept, during gestation, on a diet deficient in pteroylglutamic acid Similar cardiovascular anomalies have been observed in the offspring of rats fed galactoflavin (a riboflavin antimetabolite) during gestation (Baird et al).

It is well established that the cardiac musculature shares with the skeletal muscle the greatest impact of alpha-tocopherol deficiency Myocardial changes have been demonstrated in rats, rabbits, and calves Necrosis, loss of striations of myofibrils, nuclear pyknosis, and karyorrhexis, followed by inflammatory reaction and then by fibroblastic proliferation and scarring, is the sequence of changes most frequently encountered. Calcification of fibers has been described in some instances The accumulation in myofibrils of ceroid before necrosis takes place, and the presence of acid-fast laden macrophages are characteristic features of the myocardial damage that ensues in the vitamin E–deficient state.

Comparable disseminated myocardial lesions

have been described in ducklings placed on biotin-deficient diets and in guinea pigs kept on a diet deficient in ascorbic acid. Rinehard and Mettier used guinea pigs to study the combined effect of scurvy and beta-streptococcus infection and noticed, both in the myocardium and in the valvular endocardium, lesions which resembled Aschoff bodies. They suggested that rheumatic fever might be a response of scorbutic tissue to streptococcal infection, but similar changes were obtained by others in ascorbic acid deficiency alone.

Myocardial changes have not been found in animals deficient in *niacin* or in *vitamin* B_{12} (Follis 1956). Tissue slices of ducklings kept on *pantothenic acid*–deficient diets have shown lowered oxygen consumption and pyruvate utilization. Coenzyme A reduction was also lowered as much as 80 per cent, both in the atria and ventricles, in the absence of structural alterations. A reduction in transaminase activity in heart tissue homogenates has also been shown in pyridoxine-deficient rats but, as in the case of the pantothenic acid–deficient animal, the metabolic disorder is not accompanied by demonstrable anatomic lesions.

Among the nutritional deficiency states affecting the heart, major interest has revolved about the effect of *thiamine* deficiency. Deficiency of the thermolabile portion of the vitamin B complex has long been recognized as the chief cause of beriberi. Cardiac failure is one manifestation of this deficiency; the so-called "beriberi heart." Clinical and experimental evidence leaves little doubt that the functional disorder results from a structural defect. However, the character of the anatomical change in the human heart is still a matter of dispute. There is controversy whether the chambers of the right side are both hypertrophied and dilated or merely dilated. According to Vedder the heart is always considerably enlarged, particularly on the right side. The average weight reported by Dock was 629 Gm. On the other hand, in the series of Weiss and Wilkins (1937) the weight of the heart was normal in 21 of 30 autopsied patients. Keefer and Wenckebach (1938) both state that the right ventricle is often dilated, most prominently in the region of the pulmonary conus.

Histologically, loss of striations, fragmentation, hydropic or fatty degeneration, necrosis, sarcolysis of myocardial fibers, separation of muscle bundles by edema fluid, swelling of collagen, perivascular edema, and occasionally small lymphocytic and leucocytic infiltrations have been noticed by several investigators. Smith and Furth and Toreson have postulated that certain cases of endocardial and subendocardial fibrosis in young adults which cannot be explained on the basis of arteriosclerosis, hypertension, or rheumatic heart disease, might represent a variant of "beriberi heart" caused by prolonged dietary deficiency.

Among the various changes, particular attention has been called to the hydropic degeneration of the myofibrils and to the interstitial edema. It has been suggested that these alterations are due to water retention in the cardiac muscle. However, Jolliffe and Goodhart found no difference in the water content of human hearts in nutritional-deficient states with or without heart failure, or in organic heart disease with anorexia, as compared with the water content of the hearts in a normal control group.

Since *alcohol addicts* consume an inadequate amount of many of the essential elements of nutrition, it is not surprising that they may undergo cardiovascular disturbances similar in many respects to those described in patients with beriberi heart. The morphologic counterpart was found also to be similar and Oppenheim does not hesitate to interpret the myocardial alterations of patients with liver cirrhosis as manifestations of a hepatogenic metabolic disorder. As in beriberi heart, these myocardial alterations are not pathognomonic and it must not be assumed that they are produced merely by thiamine deficiency. However, the contention that thiamine deficiency in the human being leads to myocardial damage is well supported by observations on experimental animals. Microscopic lesions have been demonstrated in animals of various species placed on thiamine-deficient diets. These experimental lesions also, although characteristic, are not specific or pathognomonic, consisting mainly of vacuolization and necrosis of myofibrils in the early phases, and of fibrosis and scarring in animals with a longer survival period.

Large amounts of sodium pyruvate accumulate in the absence of thiamine, it has been indicated, however, that it is not the excess of

pyruvate which causes the cardiac disturbance in thiamine deficiency.

The close similarity of the cardiac lesions resulting from deficiency of potassium or thiamine has been emphasized by several investigators Well-established also is the intimate relationship of both potassium and thiamine to carbohydrate metabolism. More severe alterations should therefore be expected to occur when both essential nutrients are deficient in the diet. On the contrary, well-conducted experiments have shown a mutually protective effect of combined potassium and thiamine deficiencies

In addition to the fact that thiamine deficiency may be a primary cause of cardiac disorder, it must be pointed out that organic heart disease per se may constitute a conditioning factor in the development of thiamine deficiency. Anorexia is frequently associated with congestive failure. Congestive changes in the liver, stomach, and intestines are frequently superimposed features. All these disturbances unavoidably lead to restriction of food intake and impaired absorption and utilization. Further depletion of thiamine stores can also be expected to occur following mercurial diuresis, and if the deficiency reaches a level which is incompatible with the structural integrity of the cardiac muscle, it is obvious that the added damage will aggravate the underlying cardiac condition

CLINICAL ASPECTS OF VITAMIN DEFICIENCIES

GENERAL CONSIDERATIONS

Vitamin deficiencies may be classified as *primary* and *secondary* deficiency states. The single responsible factor in the "primary" state of deficiency diseases appears to be a chronically deficient diet. Secondary deficiency disease is caused or *precipitated by a recognizable disease without a grossly deficient* diet. The main factors in the development of secondary deficiency are (1) loss of vitamins (diarrhea, polyuria), (2) increased requirement due to elevated metabolism (fever, thyrotoxicosis, infections, pregnancy, growth, and excessive physical activity); (3) faulty absorption, utilization, and assimilation (gastrointestinal diseases, diseases of the pancreas, and disorders of the liver), (4) inability to store vitamins (diseases of the liver) These conditions may be present as single factors or in a combined form. "Secondary" deficiency diseases are more common, in a series of 50 consecutive patients, who had vitamin deficiencies and who were treated by the author, 46 were found to belong to this group (Braun and Kornbluth)

Vitamin deficiencies are known *to cause functional* or structural changes in the gastrointestinal tract and the liver, thus interfering with the normal utilization of vitamins and aggravating the deficiency syndrome Though some of the conditioning factors may be *apparent*, it has been demonstrated that, in a group of persons consuming identical diets, some develop vitamin deficiency while others do not It is probable, therefore, that intrinsic factors are also involved in the *pathogenesis* of deficiency diseases The vitamin requirements may vary considerably with the type of diet ingested *Thiamine* requirements are higher on the high-carbohydrate, low-fat diet of the Orient than on the usual Western diet (see Part 2, Chap. 31) A carbohydrate- or maize-rich diet may provoke the appearance of vitamin B deficiencies (thiamine, niacin) because of the increased need for *cocarboxylase* (*thiamine* pyrophosphate) and *coenzymes I and II*, which are essential for the breakdown of carbohydrates. *Patients with* disturbed carbohydrate metabolism, as in *diabetes mellitus*, may require larger amounts of the B *vitamins*, especially when the carbohydrate intake is increased, as in the treatment of diabetic acidosis

Replacement of food by *alcohol* may lead to the development of deficiency manifestations because of decreased intake of proteins, thiamine, *niacin*, and *riboflavin* Finally, climate could be considered a *factor in this* development Hyperthermia *increases the* rate of catabolic processes in the body, and it has been shown that the amount of thiamine necessary *for* utilization of 1 Gm of food at a temperature of 91°F *is* twice as large as that required at a temperature of 61°F.

According to Darby, the spectrum of *nutriture* (condition as to nourishment) *ranges* from the zone of excess to that of clinically manifest *severe deficiency* disease The following zones have been defined. (1) excess zone; (2) saturated zone, (3) unsaturated *and functionally* unimpaired zone, (4) potential *deficiency* disease; (5) latent deficiency disease, and (6) *clinically* manifest deficiency disease. The last three zones are of importance to this study and will be *dealt* with more fully. "Potential deficiency disease" *is a syndrome* which

exists without any clinical signs of vitamin deficiency but in which a new stress will cause a rapid development of the clinical manifestations. Biochemical tests, tolerance or saturation, will show evidence of a decreased reserve of vitamin stores.

"Latent deficiency disease" is the mildest clinically detectable deficiency state. It is characterized by nonspecific symptoms, such as irritability, gastrointestinal disturbances, and insomnia. The diagnosis is established by the aid of biochemical tests and by therapeutic trial.

The "clinically manifest deficiency diseases" include those mild and severe states which show specific functional and structural alterations.

Deficiency diseases are rarely the result of one single vitamin deficiency. *Beriberi* patients may show signs of niacin deficiency, and *pellagra* patients often show signs of riboflavin deficiency. Insufficient intake of vitamins is often accompanied by nutritional macrocytic anemia or edema due to hypoproteinemia One example of this type of disorder is *kuashiorkor*, a disease characterized by *hypoproteinemic edema* and *pellagrous dermatitis* (C. D. Williams, 1953). It should be emphasized, however, that total caloric depletion is rarely accompanied by deficiency syndromes.

THIAMINE DEFICIENCY (BERIBERI)

Definition. The clinical syndrome of thiamine deficiency is characterized by the following manifestations. cardiovascular involvement, multiple neuropathy, and edema. These manifestations are curable by thiamine administration.

Pathogenesis. *Thiamine* is a water-soluble, heat-labile vitamin, the daily human need of which is about 2 mg. Thiamine serves as a part of the enzyme cocarboxylase, which is thiamine pyrophosphate, and functions in the breakdown of glucose. The principal sources of this vitamin are lean meat, whole cereals, nuts, yeast, and legumes Polished rice and refined cereals are practically devoid of the vitamin

In the *Oriental population,* beriberi is usually due to inadequate diet and seems to be one of the pure forms of thiamine deficiency Major outbreaks of beriberi have been observed in China, Japan, Brazil, South Africa, the Philippines, and Malaya The importance of polished rice as a contributory factor and the rice pericarp as a preventive, was recognized early in the history of this disease. In the United States, the "maladies des jambes" resembles the Oriental beriberi, and is also the result of a diet consisting mainly of polished rice (Scott and Herman).

Occidental beriberi is most frequently a result of chronic alcoholism. It has been demonstrated that alcohol per se does not play a direct role in this disease, since the clinical picture could be completely reversed by administration of thiamine to patients who maintain their usual intake of alcohol. Furthermore, the disease has been observed in alcoholics even after a period of several months of total abstinence from alcohol. Because of its high caloric value and the harmful effects it has on the gastrointestinal tract, alcohol is an important predisposing cause of thiamine deficiency. Fatty degeneration or atrophic cirrhosis of the liver may interfere with the proper assimilation and storage of this vitamin Alcoholic beriberi develops more frequently in persons consuming "hard liquor," such as gin or whisky, but is also found among heavy beer drinkers. In a series of 22 patients with alcoholic beriberi, excessive physical activity was felt to be a contributory factor, inasmuch as all but six were engaged in heavy physical work (Benchimol and Schlesinger).

Clinical Features. Cardiac and nervous manifestations in the Western Hemisphere are essentially the same as those occurring in the Orient, being influenced by the degree and duration of the deficiency state and the rapidity with which the avitaminosis develops. The clinical picture may appear as one of three types· (1) *cardiovascular beriberi,* which appears in an acute, subacute, and chronic form, (2) *wet beriberi,* in which anasarca is a prominent feature; and (3) *dry beriberi,* in which the involvement of the nervous system is predominant. These three forms may appear separately or may be combined *Shoshin* is an acute form characterized by severe dyspnea, tachycardia, restlessness, water retention, and precordial pain. Unless treated immediately, patients with this syndrome die within 3 days from circulatory collapse Aalsmeer and Wenckebach and Weiss and Wilkins have described the symptoms and signs of the subacute and chronic forms of beriberi. Whereas the former have noted only right-sided failure in the Orient, the latter have observed patients with both left- and right-sided failure in the Occident. The patient is nervous and restless, and complains of fatigue and pain over the

calf muscles, which are enlarged and hard. *Precordial pain, palpitation,* and *shortness of breath* may be present. Upon examination, the skin is warm and there is often high temperature. Varying degrees of *dyspnea* and *edema* are noted The heart is usually enlarged on percussion to both right and left. There are visible and palpable pulsations over the precordium, at the left of the sternum. *A triple rhythm*, a weak 1st sound, and *systolic as well as diastolic murmurs*, may be heard The pulse is frequently rapid, but bradycardia was also noted. The blood pressure may be elevated, normal, or low. An increased pulse pressure with a *water-hammer* type of pulse may be present, and *pistol-shot sounds* may be heard over the femoral artery. Signs of right heart failure, e.g, neck vein congestion, enlarged painful liver, and serous effusion, are frequently found The phenomena of peripheral arterial vasodilatation, however, may be absent, and the clinical picture may simulate other types of heart disease

The venous pressure is markedly elevated, circulation time is generally normal or only slightly prolonged However, Benchimol and Schlesinger noted a prolonged circulation time in about half of their patients *Bradycardia*, associated with other signs of vagal activity, such as hyperactive carotid sinus, was observed during convalescence

Roentgenological examination may reveal either cardiac enlargement (Fig 16-12) or a normal silhouette. Aalsmeer and Wenckebach emphasized the dilatation of the right heart with a prominent pulmonary artery, similar to the profile of the heart in mitral stenosis In the Occident, however, cardiac enlargement of both the left and right heart chambers is more frequent, and pulmonary congestion is present in most cases The cardiac dilatation is not always completely reversible following treatment, apparently due to structural and irreversible myocardial involvement which prevents complete normalization

Fig 16-12. A Case of beriberi The cardiac shadow is enlarged to both the left and right. The hilar markings are increased, congestion of the lung at the right base B After treatment with thiamine, the cardiac shadow became normal and the lung markings decreased

Electrocardiographic Changes. In *Oriental beriberi*, the electrocardiogram is often normal or shows only a shortening of the P-R interval In *Occidental beriberi*, the electrocardiogram may show various abnormalities which are nonspecific in about 90 per cent of patients These changes represent an important feature of Occidental beriberi. They consist mainly of abnormal ... *T waves inverted.* ... be prolonged The S-T segment is generally isoelectric. The ventricular complexes are of *low voltage*, and *intraventricular conduction disturbances* may occur (Fig 16-13). These changes disappear with varying rapidity following specific treatment Electrocardiographic signs of left ventricular hypertrophy were present in about 50 per cent of the cases in a series. It may be difficult to distinguish these cases from the average hypertensive patients, particularly because the blood pressure is sometimes elevated in beriberi heart disease. A temporary

exists without any clinical signs of vitamin deficiency but in which a new stress will cause a rapid development of the clinical manifestations. Biochemical tests, tolerance or saturation, will show evidence of a decreased reserve of vitamin stores.

"Latent deficiency disease" is the mildest clinically detectable deficiency state. It is characterized by nonspecific symptoms, such as irritability, gastrointestinal disturbances, and insomnia. The diagnosis is established by the aid of biochemical tests and by therapeutic trial.

The "clinically manifest deficiency diseases" include those mild and severe states which show specific functional and structural alterations.

Deficiency diseases are rarely the result of one single vitamin deficiency. *Beriberi* patients may show signs of niacin deficiency, and *pellagra* patients often show signs of riboflavin deficiency. Insufficient intake of vitamins is often accompanied by nutritional macrocytic anemia or edema due to hypoproteinemia. One example of this type of disorder is *kwashiorkor*, a disease characterized by *hypoproteinemic edema* and *pellagrous dermatitis* (C. D. Williams, 1953). It should be emphasized, however, that total caloric depletion is rarely accompanied by deficiency syndromes.

THIAMINE DEFICIENCY (BERIBERI)

Definition. The clinical syndrome of thiamine deficiency is characterized by the following manifestations: cardiovascular involvement, multiple neuropathy, and edema. These manifestations are curable by thiamine administration.

Pathogenesis. *Thiamine* is a water-soluble, heat-labile vitamin, the daily human need of which is about 2 mg. Thiamine serves as a part of the enzyme cocarboxylase, which is thiamine pyrophosphate, and functions in the breakdown of glucose. The principal sources of this vitamin are lean meat, whole cereals, nuts, yeast, and legumes. Polished rice and refined cereals are practically devoid of the vitamin.

In the *Oriental population*, beriberi is usually due to inadequate diet and seems to be one of the pure forms of thiamine deficiency. Major outbreaks of beriberi have been observed in China, Japan, Brazil, South Africa, the Philippines, and Malaya. The importance of polished rice as a contributory factor and the rice pericarp as a preventive, was recognized early in the history of this disease. In the United States, the "maladies des jambes" resembles the Oriental beriberi, and is also the result of a diet consisting mainly of polished rice (Scott and Herman).

Occidental beriberi is most frequently a result of chronic alcoholism. It has been demonstrated that alcohol per se does not play a direct role in this disease, since the clinical picture could be completely reversed by administration of thiamine to patients who maintain their usual intake of alcohol. Furthermore, the disease has been observed in alcoholics even after a period of several months of total abstinence from alcohol. Because of its high caloric value and the harmful effects it has on the gastrointestinal tract, alcohol is an important predisposing cause of thiamine deficiency. Fatty degeneration or atrophic cirrhosis of the liver may interfere with the proper assimilation and storage of this vitamin. Alcoholic beriberi develops more frequently in persons consuming "hard liquor," such as gin or whisky, but is also found among heavy beer drinkers. In a series of 22 patients with alcoholic beriberi, excessive physical activity was felt to be a contributory factor, inasmuch as all but six were engaged in heavy physical work (Benchimol and Schlesinger).

Clinical Features. Cardiac and nervous manifestations in the Western Hemisphere are essentially the same as those occurring in the Orient, being influenced by the degree and duration of the deficiency state and the rapidity with which the avitaminosis develops. The clinical picture may appear as one of three types: (1) *cardiovascular beriberi*, which appears in an acute, subacute, and chronic form; (2) *wet beriberi*, in which anasarca is a prominent feature; and (3) *dry beriberi*, in which the involvement of the nervous system is predominant. These three forms may appear separately or may be combined. *Shoshin* is an acute form characterized by severe dyspnea, tachycardia, restlessness, water retention, and precordial pain. Unless treated immediately, patients with this syndrome die within 3 days from circulatory collapse. Aalsmeer and Wenckebach and Weiss and Wilkins have described the symptoms and signs of the subacute and chronic forms of beriberi. Whereas the former have noted only right-sided failure in the Orient, the latter have observed patients with both left- and right-sided failure in the Occident. The patient is nervous and restless, and complains of fatigue and pain over the

water retention. Metabolic studies suggest that *increased cellular osmolarity* caused by the accumulation of pyruvate and lactate ions in the tissues may be the primary factor provoking retention of sodium and water.

Excessive posterior pituitary secretion and increased aldosterone production may contribute to the salt retention, just as in the low output type of heart failure. Guggenheim studied the effect of water load in thiamine-deficient animals, he found that the impaired ability of the liver to inactivate the antidiuretic hormone is an important factor in the development of beriberi edema. Since nutritional cirrhosis occurs frequently in beriberi, these experiments appear to have some clinical confirmation.

Metabolic Changes in the Heart Muscle. Metabolic disturbances occurring in the myocardium have been implicated in the causation of heart failure. Since thiamine diphosphate serves as a cocarboxylase in the oxidation of pyruvic acid, *the characteristic derangement* of the beriberi heart is *inadequate breakdown of pyruvate from the heart.* Raab (1955) believes that thiamine deficiency is characterized both by deficient oxidation of myocardial pyruvate and exaggerated accumulation of catecholamines in the heart muscle (Chap. 10 and Part 2, Chap. 29). He states that the cardiac manifestations can be explained by these changes It is at present the consensus, however, that neither the structural nor the metabolic changes in the myocardium are sufficient per se to explain the sequence of events leading to the heart failure of beriberi. As previously stated, a peripheral vascular mechanism must also be taken into consideration

Pathological Findings. The alterations of the myocardium have been studied extensively, but no pathognomonic picture has been revealed *Dilatation* and *hypertrophy* of both the left and the right heart chambers may be found at autopsy. Generally, the myocardial lesions are not marked and consist of *mild interstitial and intracellular edema*, and *degenerative changes* This would not account for the myocardial failure Autopsy findings, moreover, may be completely normal, particularly in the very acute phases, when the metabolic derangement leads to death prior to the development of anatomically recognizable lesions In animal experiments, on the other hand, deprivation of vitamin B_1 causes *necrosis of muscle fibers* and cellular infiltration and proliferation, as well as moderate fibrosis in the atrial musculature.

Diagnosis Diagnosis is based on the history of poor dietary intake, sometimes with chronic alcoholism, signs of congestive heart failure of the high output type, elevated venous pressure, normal circulation time with increased pulse pressure, and warm skin. Laboratory examinations show electrocardiographic *abnormalities* and roentgenological changes. The absence of pericardial, valvular, or other forms of heart disease is diagnostically important. In the differential diagnosis, the various conditions leading to high output failure, e g , hyperthyroidism, cor pulmonale, arteriovenous fistula, anemia, and Paget's disease, should be considered.

Many laboratory procedures have been used for the diagnosis of thiamine deficiency The *load test* determines the urinary excretion of thiamine in 4 hr following standardized doses of the vitamin. Diminished urinary excretion of the vitamin is characteristic of deficiency Tests based on an impairment of the metabolism of pyruvic acid seem to be more reliable for the diagnosis of thiamine deficiency. Elevated blood pyruvic acid values (over 1.2 mg/100 ml) are frequently found in beriberi To increase the sensitivity of this test, administration of glucose and the performance of exercise have been advocated

Treatment. Curative treatment should be given parenterally in the acute stage. *Ten to fifty* milligrams of thiamine hydrochloride should be administered Once response has begun oral administration, 5 mg three times a day, *should be instituted. Allergic reactions to* parenteral vitamin B_1 administration have been reported. A concentrated protein-rich diet should be given simultaneously, alcoholism should be treated and faulty dietary habits corrected. Other accompanying deficiency diseases have to be treated specifically Some investigators suggest the use of *digitalis* when signs of peripheral *congestion* are present, while others claim that this drug is ineffective

Prognosis. Prognosis depends upon the progress of the disease. In the very acute form (*shoshin*), the prognosis *is bad* unless proper therapy is immediately instituted In the less acute forms, therapy results in a *rapid remission* of symptoms and signs Lack of response

Fig. 16-13. Intraventricular block in a case of vitamin B deficiency. *The first electrocardiogram shows widened ventricular complexes and isoelectric T waves. The second electrocardiogram, after nine days of treatment with thiamine and niacin, is normal.*

deterioration of the electrocardiogram in some cases, in spite of clinical improvement, has been noted. Arrhythmias are rarely seen.

Pathologic Physiology. Weiss and Wilkins and Porter and Downs stressed the peculiar state of the circulation, which is a combination of overactivity and failure of the heart. They described the *rapid velocity of blood flow*, the *dilatation of the arterioles*, and the *small arteriovenous oxygen difference* The similarity of this syndrome to thyrotoxic heart disease and to the failure which occurs in large systemic arteriovenous fistula was stressed The common characteristic feature in these disease states is a reduced peripheral resistance. Hemodynamic studies made possible by cardiac catheterization have confirmed the finding that *the cardiac output in beriberi is elevated* Burwell and Dexter were the first to study a patient with beriberi disease by this method. They found a small arteriovenous oxygen difference, a twofold elevation of right ventricular and pulmonary arterial pressure, and a markedly increased cardiac output. After treatment with vitamin B_1, there was normalization of cardiac output and pressures. Lahey et al. observed normal right heart and pulmonary arterial pressures with markedly increased cardiac output and a small arteriovenous oxygen difference. A remarkable observation in their study was the *very high peripheral venous pressure while right atrial pressure was normal.* This right atrial–peripheral venous pressure gradient is *the reverse* of that usually seen in right heart failure with low cardiac output. The fall of the peripheral venous pressure after thiamine administration with an unchanged *mean* atrial pressure, together with the above finding, suggested that the early peripheral venous hypertension was largely *the result of transmission of the arterial pressure through a dilated arteriolocapillary bed.* In arteriovenous fistula, a similar shunt occurs directly from a large artery to a large vein, but the venous valves block widespread transmission of the arterial pressure. No such protection exists in beriberi in the capillary bed and the effect therefore becomes generalized. Further, the increased capillary pressure favors the development of edema, even before the right heart is embarrassed by the excessive venous return and before the end diastolic ventricular pressure becomes elevated. This conforms with the observation that congestion and edema may be present even with normal-sized hearts Compensatory *hypervolemia* may be present, and this may lead to an increased inflow load and eventually to overstretching of the myocardium and frank failure. It follows, therefore, that *high output circulatory failure* may be observed with normal or with elevated right ventricular pressures (Youmans). These hemodynamic changes explain the increased sensitivity to injected epinephrine which had already been noted by Shimazono. Administration of a vasoconstrictor drug may cause a sudden shift of a large amount of blood from the systemic circuit into the already engorged pulmonary circulation, thus elevating the pulmonary capillary pressure to edema level

The mechanism of the *salt and water retention* in this type of high output circulatory failure has been studied (Isen et al.; Lahey et al). *It was found* that the ratio of the renal blood flow to the systemic flow was greatly *decreased* and an oliguric response to a water-load test was noted These authors assumed that the alteration in the distribution of volume flow as a consequence of shunting blood away from the kidney is responsible for the salt and

sociated with normal electrocardiograms. Since niacin is the chemically active fraction of coenzymes I and II, which are essential for the intermediate metabolism of the carbohydrates, it was assumed that *the electrocardiographic changes are the result of an altered metabolic state* in the heart muscle. This view is supported by the fact that a marked diminution of coenzyme I was found in the *striated muscle* of human subjects deficient in niacin (Axelrod et al.). In another study, electrocardiographic abnormalities occurring during the convalescent period of typhoid fever were investigated (Braun and Grossowitz). It was shown that alterations of the ST-T segment occurred concomitantly with the reduction of the urinary excretion of niacin in 35 out of 50 patients with typhoid fever. These observations and the favorable effect of niacin on the electrocardiogram were considered as evidence that electrocardiographic abnormalities are due to niacin deficiency. Finally, in experiments on the isolated perfused heart, the administration of the niacin antagonist, 3-acetylpyridine, caused marked electrocardiographic abnormalities which could be prevented or abolished by niacin administration (Braun, 1949).

Summarizing, it seems that pellagra is accompanied by specific electrocardiographic changes, but there is no evidence of hemodynamic alterations in the cardiovascular system

DISEASES PROBABLY RELATED TO VITAMIN B OR NUTRITIONAL DEFICIENCY

Increased attention is being given to certain obscure cardiopathies and their relation to nutritional deficiency Bedford and Konstam described a series of 40 African soldiers with cardiomegaly and signs of heart failure. Autopsy in 17 of the cases revealed endocardial fibrosis, some subendocardial necrosis, and a hypoplastic aorta. The coronary arteries were normal The origin of the disease could not be established but they considered nutritional or constitutional factors as causative. Davies and Ball observed a very similar condition in African natives *Endomyocardial fibrosis* was found to be the cause of death in 32 of 231 consecutive autopsies in Uganda (Chap. 12). A disease seen in Bantus and other tribes of South Africa, which has been called *cardiovascular collagenosis*, belongs in the same class. In the Occident, a similar condition has been observed (Byron). Smith and Furth described a patient with cardiac fibrosis involving the subendocardial layers of both ventricles and associated with mural thrombosis. Dock described five cases of marked cardiac hypertrophy with mural thrombosis and embolic accidents involving the systemic and pulmonary circulation. *In all these conditions, nutritional deficiency, particularly of the B vitamins, was suspected as a causative factor.*

Congenital fibroelastosis occurs very early in life and the large majority of patients die in the first year. It is frequently accompanied by other congenital anomalies of a serious nature, mainly aortic lesions. There are apparently two varieties of the disease, fetal and infantile. The latter is less frequently accompanied by congenital lesions and the chances of survival in childhood are better. The nutritional aspects of this disease have not yet been extensively investigated, but nutritional failure of the pregnant woman has been suspected as a cause, even though so far definite proof is missing

CLINICAL ASPECTS OF ANEMIA, MALNUTRITION, AND BERIBERI HEART DISEASE

The importance of certain nutritional disorders as causative factors in heart disease has been pointed out in the medical literature, emphasizing the practical therapeutic implications which result from a more precise diagnosis of these conditions

It is known that a number of deficiency states may be *solely* responsible for cases of advanced congestive heart failure as observed in beriberi heart disease (Benchimol) and in the so-called "nutritional heart disease" recently described in South Africa by Gillanders and by Higginson et al. The latter have attributed this syndrome to a dietary deficiency, since the clinical picture could be partially or completely reversed by an adequate diet.

Of greater importance, although neglected in most textbooks of cardiology, is the contributory role of these factors in the unfavorable course of certain cases of heart failure, pri-

to therapy has been noted in some cases and was attributed to irreversible myocardial damage.

PELLAGRA

Pellagra is a deficiency syndrome characterized by dermatitis, glossitis, dementia, and diarrhea.

Pellagra is the result of *niacin* deficiency. Protein depletion is a contributory factor, since it has been demonstrated that the amino acid tryptophan may serve as a precursor of niacin. Pellagra appears frequently as a secondary deficiency state.

Cardiovascular symptoms have been observed in pellagra, particularly in the acute form. The symptoms are *dyspnea on exertion* and *palpitation*. Cardiac enlargement and venous congestion have not been noted. *Electrocardiographic abnormalities* consisting mainly of alterations of the ST-T segment have been described by Feil in about 40 per cent of patients but were attributed to B_1 deficiency. Mainzer and Krause suspected a causal relationship between the electrocardiographic abnormalities and niacin deficiency. In one of their patients, the administration of niacin was followed by normalization of the electrocardiogram. Various abnormalities of the ST-T segment were demonstrated by Rachmilewitz and Braun (1945a) in 18 of a series of 27 patients with pellagra (Fig. 16-14). Therapeutic tests carried out in various phases of the disease proved that the electrocardiographic abnormalities promptly disappeared following treatment with *niacin* while administration of thiamine had no visible effect. They observed that there was a parallelism between the electrocardiographic abnormalities and the visceral manifestations of the disease. The most striking changes were seen in patients having mental and gastrointestinal disturbances, sometimes in the absence of dermatitis. On the other hand, the presence of skin lesions alone in chronic pellagrins who show no obvious involvement of the visceral organs may be as-

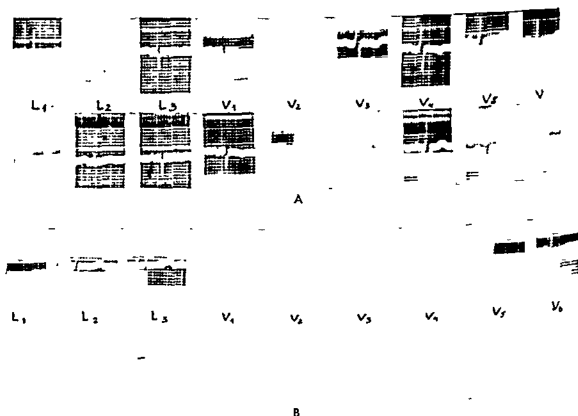

Fig. 16-14. A. Electrocardiogram in a case of pellagra. Note isoelectric and inverted T waves in the upper record. After treatment with niacin, the T waves became normal (lower record). B. Electrocardiographic abnormalities appearing during convalescence from typhoid fever. In the upper record the Q-T interval is prolonged and the T waves are inverted in L_1 and in the chest leads. After 4 days of treatment with niacin, the electrocardiogram shows normal ST-T segments (lower record).

of appropriate medication, a fact which has been attributed to the occurrence of irreversible hypertrophy.

Figure 16-15 illustrates the decrease in heart size observed in a patient with hookworm anemia following the normalization of the blood count and hemoglobin level as a result of the oral administration of ferrous sulfate.

The mechanism of cardiac enlargement in anemia has not yet been established. The present trend is to consider this type of cardiomegaly as a nutritional deficiency of the myocardium due to chronic hypoxia (Lewis et al.), although one cannot discard the effect of the hemodynamic changes which overload the heart. In favor of this are the clinical observations of Hunter; in his cases, dilatation and hypertrophy did not result from myocardial hypoxemia, since the reduction in heart size occurred in the initial stage of treatment, when the hemoglobin level was still well below normal levels These cases do not suggest an immediate improvement of the hypoxemic heart but rather the influence of the hemodynamic changes.

The heart sounds are usually altered in anemia. At the apex, the 1st heart sound is generally increased in intensity, and there is a *loud 3d sound* Murmurs appear frequently, particularly in the severe cases, and may be loud enough to simulate organic valvular disease. *Systolic and diastolic murmurs* may be heard over the entire precordium, particularly in advanced cases of sickle-cell or pernicious anemia. The systolic murmurs are due to rapid circulation, as well as to dilatation of the cardiac chambers and the AV rings. *Diastolic murmurs* are observed in anemic patients in the absence of organic heart disease, simulating either aortic insufficiency or mitral stenosis. They are due to the dilatation of the aortic and pulmonic valvular rings as well as to dilatation of the ventricles (relative mitral and tricuspid stenosis).

In addition to these cardiac murmurs, a *venous hum* may be heard over the neck veins and the supraclavicular area.

Nonspecific electrocardiographic changes may be observed, such as S-T depressions, low voltage or inversion of the T waves, and, rarely, low voltage of the QRS complex. This will increase in amplitude following appropriate therapy (Figs 16-16, 17). There is some controversy regarding the frequency and importance of the electrocardiographic changes in chronic anemia. According to a number of publications they occur in approximately 20 per cent of all cases and are usually not marked (Porter et al; Wilbus et al.) although they

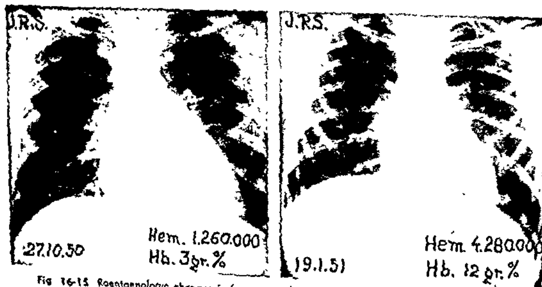

Fig 16-15 Roentgenologic changes in heart size observed in a 15-year-old patient with severe hookworm anemia Cardiac enlargement is evident in the initial x-ray film at which time the erythrocyte count was 1,260,000 and the hemoglobin level 3 Gm per cent. Following appropriate therapy there is a marked reduction in heart size, which occurred 3 months later together with a practically normal blood count

marily due to other causes. Thus, it is not rare to see a patient in failure who is refractory to the usual therapy until additional measures correct an associated deficiency state (anemia, hypoproteinemia, or thiamine deficiency).

On the other hand, these nutritional disorders may be secondary to the heart failure itself, because of several circumstances which predispose to them.

It is known that patients in failure often complain of poor appetite, either as a result of visceral congestion or of the effect of certain drugs, such as digitalis or ammonium chloride. In addition, the following factors must be taken into account: disturbances of gastrointestinal absorption, excessive diuresis due to the frequent administration of mercurial diuretics which eliminate significant amounts of water-soluble vitamins, and the dietary restrictions imposed upon these patients. The widespread indication of sodium restriction in the treatment of the congestive manifestations, although of great value in such cases, undoubtedly contributes to the unpalatability of the diet and leads to anorexia with consequent malnutrition. Finally, it should be emphasized that increased metabolic needs may supervene in decompensated patients in the course of infections, hyperthyroidism, or pregnancy, leading to the relative inadequacy of a diet which would be appropriate under normal circumstances.

The need for a proper recognition of the above-mentioned factors is emphasized by cases in which these associated conditions interfere with the effect of drugs leading to the apparent irreversibility of heart failure A number of these instances of *refractory failure* are actually due to the frequently unrecognized presence of one or more of these factors, which are usually controllable with appropriate therapeutic measures

The cardiovascular effects of the following deficiency states will be described below: (1) anemia, (2) malnutrition and starvation, including the effect of hypoproteinemia; (3) other types of deficiency, (4) beriberi

ANEMIA

Long-standing severe anemia, regardless of its origin, often results in various cardiovascular manifestations, either by causing degenerative changes in the hypoxic cardiac muscle or by overloading the heart as a result of hemodynamic changes.

Anemic states often represent aggravating or precipitating factors of heart failure in patients with other types of heart disease However, they occasionally constitute *the sole cause* of heart failure. *Any type of anemia of severe degree and of long duration may determine circulatory changes.* Thus, in sickle-cell anemia, which as a rule does not respond favorably to therapy, these changes are more marked, and may resemble rheumatic valvular disease. However, even certain reversible forms of anemia (such as pernicious anemia and the type due to hookworm infestation) often lead to cardiac involvement if they are not properly treated. It is in these conditions that the role of anemia in heart disease may be observed, since the effects on the cardiovascular system disappear rapidly following appropriate therapy.

The basic pathophysiology of the cardiovascular system in anemia is due to various adjustments in the diminished *oxygen-carrying capacity* of the blood. In order to maintain an adequate oxygen supply to the tissues, several mechanisms may operate in anemia Thus, the velocity of blood flow is *increased*, probably as a result of peripheral vasodilatation caused by the accumulation of acid catabolites, in addition to a decrease in blood viscosity.

There is also an increased percentage of oxygen utilization by the tissues, and cardiac output is considerably greater due to rapid circulation and greater venous return to the heart. *Anemic heart disease* illustrates a type of heart failure which is associated with an increased cardiac output.

Notwithstanding the greatly augmented cardiac output, the heart may not be overloaded (Stewart et al , 1937), and this is explained by a drop in peripheral resistance and a lower blood pressure resulting from vasodilatation and lowered blood viscosity. However, in cases of severe chronic anemia, the heart is generally affected, in spite of the mitigating effects of the decrease in peripheral resistance (Friedberg). The selective shunting of blood from less important areas to vital organs is also an important compensatory process in the anemic states (Porter et al., 1953).

Cardiac enlargement, one of the main effects of chronic anemia on the cardiovascular system, is partly or completely reversible by specific therapy, as proved by serial roentgenograms.

The reduction in the heart size of these patients depends upon the intensity and duration of the anemic state. In cases of long duration, cardiac enlargement may be persistent, in spite

of appropriate medication, a fact which has been attributed to the occurrence of irreversible hypertrophy.

Figure 16-15 illustrates the decrease in heart size observed in a patient with hookworm anemia following the normalization of the blood count and hemoglobin level as a result of the oral administration of ferrous sulfate.

The mechanism of cardiac enlargement in anemia has not yet been established. The present trend is to consider this type of cardiomegaly as a nutritional deficiency of the myocardium due to chronic hypoxia (Lewis et al.), although one cannot discard the effect of the hemodynamic changes which overload the heart. In favor of this are the clinical observations of Hunter; in his cases, dilatation and hypertrophy did not result from myocardial hypoxemia, since the reduction in heart size occurred in the initial stage of treatment, when the hemoglobin level was still well below normal levels. These cases do not suggest an immediate improvement of the hypoxemic heart but rather the influence of the hemodynamic changes.

The heart sounds are usually altered in anemia. At the apex, the 1st heart sound is generally increased in intensity, and there is a *loud 3d sound*. Murmurs appear frequently, particularly in the severe cases, and may be loud enough to simulate organic valvular disease. *Systolic and diastolic murmurs* may be heard over the entire precordium, particularly in advanced cases of sickle-cell or pernicious anemia. The systolic murmurs are due to rapid circulation, as well as to dilatation of the cardiac chambers and the AV rings. *Diastolic murmurs* are observed in anemic patients in the absence of organic heart disease, simulating either aortic insufficiency or mitral stenosis. They are due to the dilatation of the aortic and pulmonic valvular rings as well as to dilatation of the ventricles (*relative mitral and tricuspid stenosis*).

In addition to these cardiac *murmurs*, a *venous hum* may be heard over the *neck veins* and the *supraclavicular area*.

Nonspecific electrocardiographic changes may be observed, *such as S-T depressions*, low voltage or inversion of the T waves, and, rarely, low voltage of the QRS complex. This will increase in amplitude following appropriate therapy (Figs. 16-16, 17). There is some controversy regarding the frequency and importance of the electrocardiographic changes in chronic anemia. According to a number of publications they occur in approximately 20 per cent of all cases and are usually not marked (Porter et al.; Willius et al.) although they

Cardiac enlargement is evident in the initial x-ray film at which time the erythrocyte count was 1,260,000 and the hemoglobin level 3 Gm per cent. Following appropriate therapy there is a marked reduction in heart size, which occurred 3 months later together with a practically normal blood count.

may become more significant in severe cases (Bloch; Carter et al.; Szekely).

Precordial pain has often been described in the literature, and is considered by some as a common manifestation (Lewis; Coombs; Pickering et al.), whereas others (Willius et al.) find this symptom very rarely. Almost every case of anemia complicated by precordial pain has shown pathologic evidence of coronary atherosclerosis (Pickering et al.; Zimmermann; Hochrein; Scherf), and most authors do not believe that anemia per se may cause it. However, Cabot (1926) and Elliot (1934) described cases with perfectly normal coronary arteries.

The fact that appropriate treatment of anemia leads to a rapid and complete relief of the painful episodes indicates that anemia acts as a predisposing factor in patients with organic narrowing of the coronary arteries.

The diagnosis of heart failure in anemia is often difficult since certain symptoms, such as dyspnea, palpitations, and edema, due to the blood dyscrasia may be observed even without heart disease or failure. The presence of tachycardia, heart murmurs, gallop rhythm, and cardiac enlargement may easily mislead and cause the diagnosis of heart failure. The normal venous pressure, and the absence of pulmonary congestion and venous engorgement help in excluding failure. However, severe anemia may lead to both left and right ventricular failure followed by pulmonary and peripheral congestion. In these cases, there usually is associated heart disease but in rare cases anemia may be the sole etiologic factor. One can rule out an associated organic cardiac condition only after disappearance of the anemic state, since the latter may mask or simulate other lesions of the heart

Digitalis has been considered by McMichael as inadequate, and perhaps contraindicated, in heart failure due to anemia, because it decreases venous pressure and consequently cardiac output; however, it has been proved that venous pressure drop is mostly due to increased cardiac efficiency. Therefore, digitalis may be useful and should be given in addition to other therapeutic measures intended to correct the anemic condition. It is important to be er-

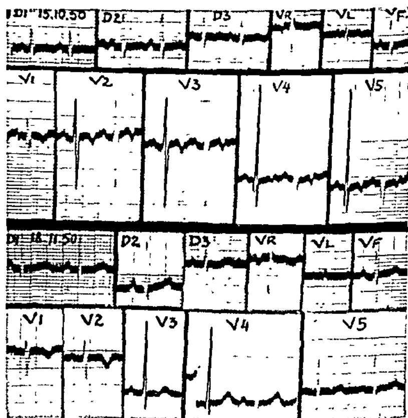

Fig. 16-16. Abnormal electrocardiogram in severe hookworm anemia. The first tracing shows primary T-wave changes and tall R waves in V_4 and V_5 (possible left ventricular dilatation). Following a 30-day period of therapy with ferrous sulfate the tracing became entirely normal.

tremely cautious with blood transfusions, since an abrupt increase in venous pressure may aggravate heart failure and cause acute pulmonary edema. If it becomes necessary to resort to transfusions, they should be given frequently but in small amounts. The prophylactic use of digitalis has been recommended to prevent an unfavorable effect of transfusions.

MALNUTRITION AND STARVATION

The influence of malnutrition and starvation on the cardiovascular system have not been properly emphasized in the medical literature, and it is a current opinion that the heart, contrary to other organs, does not exhibit significant degenerative changes or functional disturbances as a result of starvation. The decrease of body metabolism under these circumstances would tend to reduce the work of the heart by diminishing the cardiac output. As a result of this interpretation, the problems related to the effects of malnutrition did not receive much attention, with the exception of cardiac beriberi, which has been the object of numerous investigations. Lately, however, various factors have led to a modification of the above-mentioned viewpoints, particularly the disastrous effects of surgery in undernourished populations (Weiss), the study of persons liberated from concentration camps (Ellis), and the experiments on normal human volunteers, submitted to inadequate diets with the object of reproducing the poor nutritional conditions occurring in certain parts of Europe during the war (Simonson et al., Keys et al.)

The modern strict dietary treatment of heart failure, hypertension, and myocardial infarction, which involves severe caloric and sodium restrictions, has also led to a reevaluation of these problems, since such treatment may result in unfavorable effects.

According to Keys et al., a prolonged period of undernutrition results in a remarkable metabolic adaptation of the body (decrease of the basal metabolism or reduction of the total energetic metabolism). The former is presumably due to the decrease of body weight as well as the intensity of metabolic changes, whereas the latter results from a diminished activity as well as a more economic type of work. These mechanisms induce a series of compensatory changes in the cardiovascular

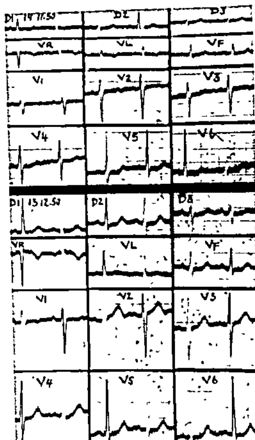

Fig. 16-17. The effects of vitamin B_{12} on the electrocardiographic abnormalities of a patient with pernicious anemia. Primary T-wave changes and low voltage of the QRS complexes are present in the first tracing. One month later the improvement is remarkable, although there is slight depression of the S-T segment in left precordial leads.

system, so that a normal individual may adjust fairly well to the effects of a marked caloric restriction (Weiss et al.).

Among the usual cardiac functional disturbances observed in advanced cases of malnutrition are *bradycardia* and hypotension (Weiss et al.; Keys). The heart rate may fall to less than 50 per minute, and in some cases has been found to be as low as 30. The rhythm is regular; respiratory arrhythmia, as well as tachycardia which normally follows physical exertion, infection, or emotion, disappears. This sign should always be taken into consideration in cachectic patients (Keys). Hypotension is common, with a decrease of systolic pressure and pulse pressure. This is particularly evident in patients with preexisting hypertension (Hellerstein et al.).

The decrease in pulse pressure apparently results from a reduction of cardiac output and stroke volume. These values decrease proportionately more than the degree of reduction in the metabolic changes of the body (Keys). There is a greater utilization of oxygen by the tissues (leading to a lower oxygen content of the venous blood) and a decrease in peripheral blood flow explaining the patient's pallor (which is out of proportion to the degree of anemia), the cold skin, slight cyanosis, and the prolonged circulation time. The venous pressure is often 50 per cent or less of its normal value.

A decrease in heart size, somewhat disproportionate to the degree of weight loss, may be seen in acute and chronic cases of malnutrition, and there usually are microscopic changes in the heart muscle, such as reduction in the size of the myocardial fibers, atrophy, and fatty degeneration (Keys et al.). The concept of cardiac atrophy on the basis of consumptive diseases has been well known for a number of years.

According to Hellerstein et al, *cardiac atrophy* is defined as an acquired reduction in volume and weight of the heart, due to several causative factors, such as neoplastic diseases, chronic infections, and metabolic disorders. The basic nature of the atrophic changes is unknown, but is thought to be the result of a process of autolysis and tissue liquefaction, catalyzed by cellular enzymes (Bradley). This type of atrophy may be observed, not only in normal hearts but in cases of preexistent cardiac hypertrophy, and is reversible following the removal of the causative factor. It is to be emphasized, however, that this reversibility is a slow process, both anatomically and functionally. This must be taken into consideration, in view of the potential dangers of a sudden increase of the metabolic demands, due to excessive food intake, which would lead to an increased cardiac load in the presence of a decreased efficiency of the heart. Under these circumstances, heart failure may occur (Hellerstein et al.; Brozek et al.), as well as complications due to increased blood pressure (Keys; Durant).

Several *electrocardiographic changes* have been described in extremely undernourished individuals (Ellis; Keys; Simonson et al.; Forster), particularly low voltage of all waves. Experimentally, in human volunteers (Simonson et al.) it was possible to observe reduction in amplitude of both atrial and ventricular complexes. The patients were normal young individuals submitted to low-calorie diets for approximately 6 months. Following this period, a high-calorie diet was given and the electrocardiograms returned to normal. A prolongation of the Q-T interval is also frequently observed in such cases, although there is no correlation with the prolongation of ventricular diastole.

During convalescence, in spite of the increase of cardiac rate, the Q-T interval remains above normal limits, and this finding is considered by Simonson et al. as one of the most persistent abnormalities in cases of malnutrition. Displacement of S-T or conduction defects are rare. There is a tendency to right axis deviation, probably due to a change in the anatomical position of the heart as a result of the decrease in size of all organs including the liver and the heart (Keys). The average duration of the above-mentioned ECG changes is from 2 to 3 weeks in the cases studied by Ellis (concentration camp prisoners), whereas the experimental observations of Simonson et al showed that a complete normalization of the tracing occurred only after 32 weeks. It is important to note, that in these cases the electrocardiographic abnormalities often became more marked during the stage of clinical improvement.

There is no satisfactory explanation for the ECG changes which appear in cases of malnutrition and starvation. Vitamin deficiencies do not seem to play a role, since it is a well-known fact that the low vitamin requirements of the hypocaloric diets are rarely conducive to the severe stages of vitamin deficiency. Regarding the electrolytic disturbances, which are undoubtedly present in these patients, the laboratory studies have not been sufficient to prove that they are responsible for the changes. Hypopotassemia and hypocalcemia have been considered, due to the similarity of their electrocardiographic effects. According to Ellis, several factors probably play a role, including protein and carbohydrate deficiencies, and a number of electrolytic disturbances.

The pathologic changes found in the heart in cases of malnutrition are not always sufficiently significant to explain the electrocardiographic abnormalities.

Cardiovascular symptoms are uncommon, even after physical exertion; there is certainly a limitation in cardiac reserve, which does not

cause symptoms following exercise, due to the tendency of these patients to collapse during physical efforts as a result of general muscular weakness.

Orthostatic dizziness and *syncope* are often present as evidence of a marked vasopressor instability. *Peripheral edema* is frequently observed, but it does not seem to be of cardiac origin, since there is no increase in heart size or venous pressure There is, however, a relative increase in circulatory blood volume and extracellular fluids in relation to the body weight The exact pathogenesis of starvation edema remains obscure in many aspects The *low protein content* of the edema fluid is a strong argument against the presence of increased capillary permeability in these cases A marked degree of *hypoproteinemia* must certainly play a role, especially the decrease in serum albumin However, certain objections were raised. Hunger edema has occurred occasionally with normal plasma proteins, and there may be no edema in cases of hypoproteinemia, moreover, the edema may begin to decrease before any change occurs in the plasma proteins. These facts are not sufficient to rule out the influence of hypoproteinemia as a possible cause of edema, since other factors (Friedberg) may also play a role, e.g., variations in tissue pressure, dehydration, and degree of physical activity It is well known that hunger edema may decrease or disappear after rest, and reappear following exertion The increase in venous return as a result of exercise may exceed the capacity of the atrophied heart, and this may cause the edema to appear or become more marked.

It is interesting to note that clear-cut cardiac failure rarely occurs in cases of malnutrition or starvation, even in the presence of long-standing dietary restrictions However, failure may be observed following rapid feeding and a correction of the electrolyte imbalance Under these conditions, dyspnea, tachycardia, venous hypertension, and increase in heart size are observed, as well as the reappearance of edema. This was initially of nutritional origin but its reappearance is caused by congestive failure Although this sequence of events may be caused by disproportion between greater metabolic demands and reduced efficiency of the heart, it is not improbable that other mechanisms may also play a role. Thus, the hypercaloric diets, particularly those due to excessive carbohydrate ingestion, encroach upon the thiamine reserves of the body and may determine a thiamine deficiency which was previously not apparent, thus leading to a typical clinical picture of cardiac beriberi.

The severe hypocaloric diets in the treatment of the advanced forms of hypertension, coronary sclerosis, and other types of cardiovascular disease, are undoubtedly of great benefit to many patients for long periods of time.

However, notwithstanding the immediate beneficial results of such diets, which are either prescribed or forced by special circumstances, *harmful effects may be observed if these restrictions are imposed for long periods of time* and may greatly overshadow the initial favorable effects. *A similar mechanism occurs in chronic constrictive pericarditis and in organic tricuspid valvular disease complicated by hypoproteinemia, notwithstanding an adequate diet.* Under these circumstances, one of the most serious effects is *hypoproteinemia*, which is increased by repeated removal of ascitic fluid. Actually, heart failure per se predisposes to a decrease in plasma proteins through various mechanisms including chronic congestion of the liver, leading to hepatic insufficiency and hepatic cirrhosis *Albuminuria*, which commonly occurs in heart failure, may contribute to the protein deficiency. Thus, it is not surprising that hypoproteinemia should occur in chronic heart failure with a decrease in serum albumin and a reduction in the albumin/globulin ratio In cases of marked protein deficiency, this may contribute to maintain the edema and, in many instances, explains the apparent irreversibility of these changes (Durant).

It is to be emphasized that the low-calorie diets lead to a greater utilization of the ingested proteins, which are used for energetic changes rather than for the nitrogen balance of the body (Stare et al.). Thus, an adequate protein intake in a low-calorie diet may prove to be relatively inadequate, whereas, in a normal diet, the protein requirements are lower

PELLAGRA

Electrocardiographic changes which closely resemble those observed in beriberi have been described in pellagra (Feil, Mainzer et al, 1946, Mainzer, 1948; Porter et al; Rachmile-

witz et al., 1944, 1945) and were initially interpreted as probably due to an associated thiamine deficiency. Mainzer and Krause (1946) described these changes in 23 cases of pellagra, some of whom reverted to normal following the administration of nicotinic acid; however, these authors did not mention the thiamine content of the hospital diet. Subsequently, Mainzer described the results of a study of 45 cases of pellagra and concluded that, although nicotinic acid deficiency may be the sole cause of the ECG changes in some cases, it was necessary to give thiamine supplements to others in order to obtain a complete normalization of the ECG.

According to Rachmilewitz and Braun (1945a), the ECG changes were seen in only some instances, all of which showed visceral involvement due to this type of avitaminosis. The main ECG abnormalities described were primary T-wave changes and S-T segment depression, all of which rapidly disappeared following administration of nicotinic acid, while they remained unchanged by thiamine treatment. It is interesting to note that, in two cases, the response to nicotinic acid was noted only after the control of an associated hypoproteinemia In the remaining nine cases, all of which exhibited the cutaneous form of the disease as their sole clinical manifestation, significant electrocardiographic abnormalities were not observed. The authors concluded that, notwithstanding the similarity of the ECG pictures, cardiac involvement in pellagra differs considerably from that of beriberi, especially in view of the absence of cardiac enlargement or evidence of heart failure. In patients with ascites and peripheral edema, hypoproteinemia was the main factor responsible.

The authors had the opportunity of studying nine cases of pellagra, three of which were associated with beriberi heart disease In the latter, it was impossible to evaluate the influence of nicotinic acid deficiency on the electrocardiographic changes However, in the six cases of uncomplicated cutaneous pellagra, the authors did not observe any type of electrocardiographic abnormality.

VITAMIN C DEFICIENCY

The lack of ascorbic acid has been pointed out as a cause of cardiac involvement in a number of experimental studies; it has been suggested as a possible factor in the pathogenesis of rheumatic fever. These observations have not been confirmed clinically, since the few instances of cardiac enlargement described in cases of scurvy were not sufficiently analyzed to rule out the possibility of an associated beriberi heart disease.

BERIBERI

A deficiency in vitamin B_1 plays an important role in cardiovascular pathology as the cause of an unusual type of heart disease which is completely reversible provided it is recognized and adequately treated in its early stages. The incidence of this type of cardiac disease has been generally underestimated. The authors believe that it is not a rare condition, since in the last 4 years they have identified no less than 63 cases of beriberi heart disease, in addition to a number of others in which thiamine deficiency played a secondary role in the course of other types of cardiac disease.

The initial observations of this condition were among the Oriental populations, as a result of dietary deficiencies (Aalsmeer et al.; Wenckebach; Keefer; Shimazono), whereas in the Western Hemisphere, most cases are due to chronic alcoholism (Weiss et al; Weiss; Goodhart et al.). This fact was brought out in the authors' observations, since all their patients, without exception, were chronic alcoholics (Benchimol, 1953; Benchimol et al, 1947, 1951, 1953). It is interesting to note that most cases of vitamin deficiencies do not occur in extremely undernourished patients, but rather in those with a high caloric intake resulting in a normal or excessive body weight. This is explained by the higher vitamin requirements of the hypercaloric diets. Carbohydrates require thiamine for their complete metabolism (Lecocq). It is well known that vitamin B_1 participates in carbohydrate metabolism as a coenzyme (cocarboxylase). (See Part 2, Chap. 31.)

Since the *polished rice diet* of the Orient and chronic alcoholism in the Western Hemisphere both represent essentially a high-carbohydrate and a low-thiamine intake, it is obvious that under either circumstance a vitamin B_1 deficiency may result, leading to beriberi heart disease. This is particularly true of chronic alcoholics having a diminished appetite and

an associated gastrointestinal disturbance which decrease the absorption of thiamine.

An interesting feature of this *condition* is that most patients are apparently well nourished, and some of them are actually *obese*. This is accounted for by the high caloric content of their diets, notwithstanding the above qualitative deficiencies

Since chronic alcoholism is so much more frequent than cardiac beriberi, it is probable that other associated factors play a role, such as physical exertion, infections, thyrotoxicosis, or pregnancy. The direct effect of alcohol on the heart muscle, leading to an "alcoholic myocarditis," *is no longer accepted as an explanation* for beriberi heart disease The clinical *manifestations in these* patients have been seen to disappear following the administration of high doses of thiamine, notwithstanding a continued alcoholic intake (Weiss) It is believed that chronic alcoholism *affects the cardiovascular system* as a result of thiamine deficiency, although it *is difficult to* say whether myocardial failure occurs as a result of interference with energy production or because of increased cardiac work resulting from the possible vasodilator effect of pyruvate (Best).

The *clinical picture* of beriberi heart disease is not confined to the classical descriptions of this *condition in* the Orient, i.e., a disorder having as its main features rapid circulation *associated* with *right* heart failure. Most cases studied in this hemisphere *do not* exhibit the hyperkinetic syndrome and often show evidence of left heart failure. Peripheral edema is one of the *earliest and most important signs* which has been observed in every patient in the authors' series, either as the *sole initial* manifestation or associated with exertional dyspnea *Signs of pulmonary congestion were* often present. *Apical systolic murmurs* (grade 1 or 2) were common and are probably due to relative mitral insufficiency.

In certain cases, a transient *diastolic murmur* was *present* which simulated aortic insufficiency. *Gallop rhythm* was a frequent finding

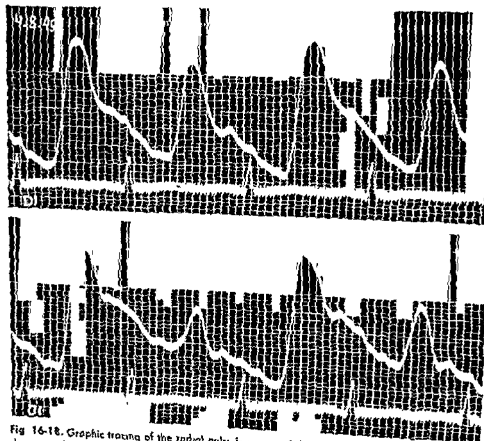

Fig 16-18. Graphic tracing of the *radial pulse* in a case of *decompensated beriberi heart disease*, showing pulsus alternans *(above)*, which is accentuated by the *Valsalva maneuver* (below).

and disappeared following recovery. An interesting feature was the lability of the heart rate, a transient and rather marked bradycardia appeared either during heart failure or in the stage of clinical improvement. *Pulsus alternans* was observed in two patients, and it was interesting to note that it occurred during clinical improvement and shortly before hospital discharge (Fig. 16-18). The *lability of blood pressure* is also typical. In certain cases, there is an *increase in pulse pressure;* in others on the contrary, there is a diastolic hypertension during the stage of congestive failure, which may persist for some time after recovery.

In one-third of the cases there may be evidence of *rapid circulation*, such as decreased circulation time; however, few cases exhibit a typical hyperkinetic syndrome with increased pulse pressure, water-hammer pulse, normal circulation time in spite of the congestive heart failure, and exaggerated cardiac pulsations at fluoroscopy.

The presence of *polyneuritis* is additional evidence of thiamine deficiency and is seldom absent.

These clinical manifestations are usually sufficient to identify beriberi heart disease, particularly in cases of chronic alcoholism However, the course of changes of the clinical picture after administration of thiamine is the most valuable diagnostic criterion.

The *roentgenologic examination* of the heart in beriberi heart disease does not show a characteristic configuration, however, a decrease in heart size following thiamine treatment is important for diagnosis. Cardiac enlargement occurs in the majority of cases with or without evidence of pulmonary congestion Either right or left chamber enlargement may predominate while diffuse dilatation occurs in some instances (Figs. 16-19, 20). Most patients exhibit a predominant enlargement of the left ventricle. The prominence of the left middle arch, observed in some cases, may simulate mitral heart disease When pulmonary congestion occurs, it is predominant in the hilar regions. The cardiac enlargement is not always rapidly and completely reversible. Depending upon the intensity and duration of the myocardial lesions, the condition may be only partially reversible or even completely irreversible. This is explained by the fact that interstitial edema and degeneration of the myocardium may lead to myocardial fibrosis which then may simulate other degenerative conditions such as coronary heart disease (Schlesinger et al.).

The *electrocardiogram* frequently reveals several abnormalities due to myocardial in-

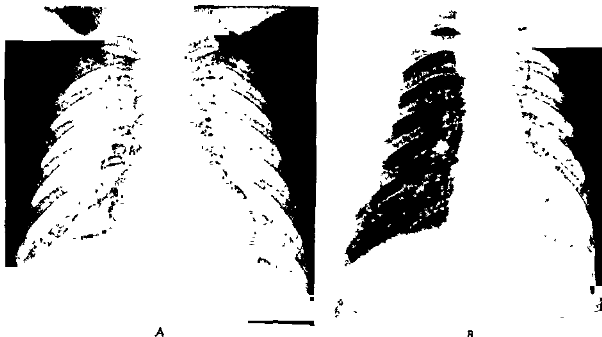

Fig. 16-19. A. The initial x-ray film reveals cardiac enlargement involving both the left and the right heart chambers. B. Two weeks later the roentgenogram has become normal.

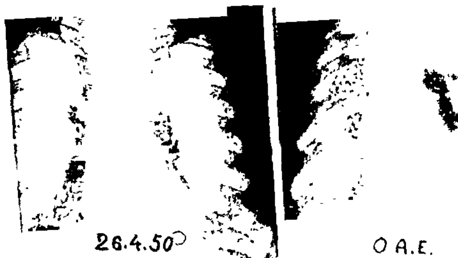

Fig. 16-20. Serial roentgenograms. Thirty-eight-year-old *chronic alcoholic*, admitted in advanced heart failure. The first x-ray film shows a considerable increase in heart size as seen in PA and LAO positions, in addition to slight dilatation of the aorta, and hilar congestion. Following intravenous thiamine therapy, the cardiac shadow is markedly decreased 1 week later, and subsequently becomes completely normal.

and disappeared following recovery. An interesting feature was the lability of the heart rate; a transient and rather marked bradycardia appeared either during heart failure or in the stage of clinical improvement. *Pulsus alternans* was observed in two patients, and it was interesting to note that it occurred during clinical improvement and shortly before hospital discharge (Fig. 16-18). The *lability of blood pressure* is also typical. Fig 16-22. A 41-year-old man with beriberi heart disease, showing initial T-wave inversion in leads I and aVL and diphasic deflection in lead V_5, in addition to signs of moderate left ventricular hypertrophy. Nine days later, these changes have become less marked, and they disappear completely in the third tracing The last electrocardiogram, recorded when the patient was fully compensated, exhibits an increase in voltage of the T waves as compared to the previous tracing

volvement. Although these changes are not specific, their disappearance following the administration of thiamine is of importance in the diagnosis and evaluation of the clinical course of these cases. Low or inverted T waves are often present, either as an isolated finding, or associated with low voltage of the QRS complexes (Fig. 16-21). In the course of clinical improvement, the T waves may become tall and peaked, possibly on account of the predominant tonus of the vagus nerve not uncommonly found in such cases. These abnormalities are not always reversible for the same reasons which were discussed in regard to the roentgenologic findings The T wave may be inverted from the outset (Fig. 16-22) and become progressively normal as the clinical picture improves, or, on the other hand, it may become more inverted during the stage of recovery from heart failure (Fig. 16-23). Disturbances in rate and conduction are not generally described. However the authors have

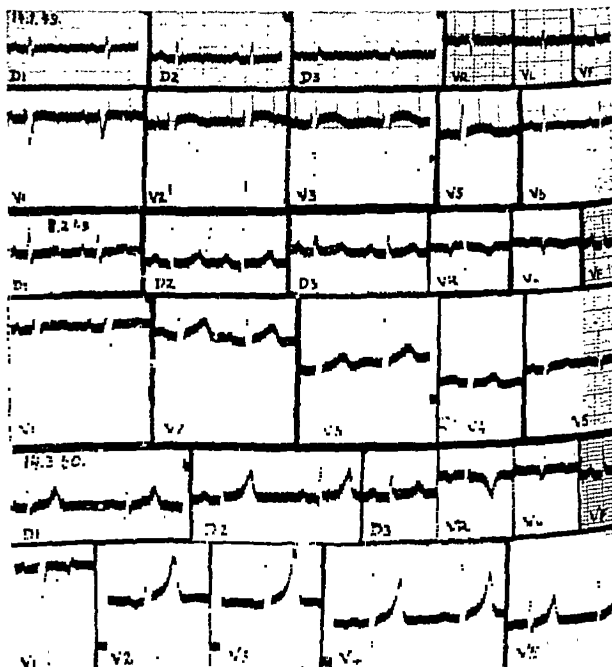

Fig. 16-21. Progressive improvement of electrocardiographic abnormalities in a 42-year-old man in *heart failure due to thiamine deficiency*. The first tracing shows low voltage of the QRS complexes and flat T waves. Three weeks later, there is an increase in amplitude of all deflections. The third ECG shows tall, peaked T waves in the standard and precordial leads.

observed a case of first-degree AV block and also a case of left bundle branch block confirmed on necropsy (Schlesinger et al). Electrocardiographic signs of left ventricular preponderance may be found and are probably explained by dilatation because they are often partly or completely reversible. This may raise the problem of differential diagnosis with hypertensive heart disease. The enlargement of the heart is occasionally reversible while the ECG changes may persist in spite of adequate treatment (Fig 16-24).

The *diagnosis* of beriberi heart disease is relatively simple in the presence of the syndrome of high output failure. However, rapid circulation may be absent and there may be left ventricular failure Then, diagnosis may be more difficult because the clinical picture resembles that caused by other types of heart disease of other origins.

Certain diagnostic features are important:

1. History of chronic alcoholism
2. The presence of other manifestations of vitamin deficiency, such as polyneuritis
3. The absence of other causative factors of heart disease
4. The favorable effects of rest and thiamine administration

The course and prognosis depend upon the intensity and duration of myocardial involvement, since the long-standing effects of thiamine deficiency may lead to an irreversible type of cardiac disease. The presence of an associated form of heart disease is an unfavorable feature, and explains why at times it may be difficult to achieve complete recovery with the usual doses of thiamine.

Certain cases, exhibiting an acute onset, were described in the Orient as *shoshin* or the "acute pernicious form" of beriberi. Patients with shoshin present sudden onset of severe heart failure with cyanosis, precordial distress, and shock, which often ends fatally after a short period. Such cases must be immediately recognized since a dramatic improvement often ensues following the intravenous administration of thiamine.

The failure of favorable response to thiamine therapy does not necessarily rule out the diagnosis of beriberi in any case of heart disease, as several authors have repeatedly emphasized (Alleman et al; Blankenhorn, 1948; Blankenhorn et al, 1946; Vilter).

The authors' observations indicate that beriberi heart disease under certain conditions is followed by diffuse myocardial fibrosis, with electrocardiographic changes which closely resemble those caused by chronic coronary insufficiency or other types of myocardial disease.

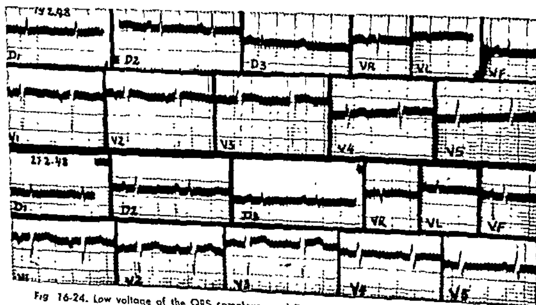

Fig 16-24. Low voltage of the QRS complexes and T waves of a 33-year-old patient with irreversible beriberi heart disease. Notwithstanding thiamine therapy, there was no clinical response, and the second tracing, taken one week later, remained unchanged The diagnosis of this case was confirmed by post-mortem examination.

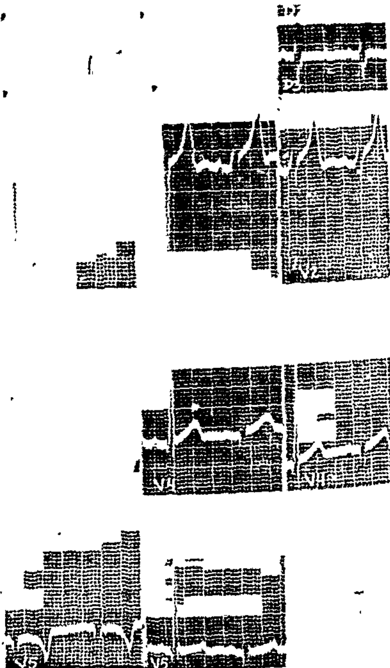

Fig. 16-23. Serial electrocardiograms of a 38-year-old *chronic alcoholic* (male) in heart failure. The initial tracing shows *primary T-wave* changes with evidence of left ventricular hypertrophy. The second electrocardiogram, *recorded* 20 days later, during clinical improvement, reveals an accentuation of the T-wave changes with inversion of this deflection which becomes more marked on *6/28/1949*, in addition to an *increase* in voltage of the R waves in leads V_4 and V_5. The subsequent electrocardiograms show *progressive* improvement of the T-wave abnormalities. In the last tracing, these deflections have become normal and upright, although there are persistent signs of left ventricular hypertrophy.

the authors do not believe in the routine use of digitalis in beriberi heart disease, this drug may be given, not only in cases of associated heart disease, but also when there is a diagnostic problem and the administration of thiamine is not rapidly effective. This procedure seems especially justified in cases of severe heart failure, in which all available measures should be attempted It should also be emphasized that bed rest alone is often beneficial, although most patients require the administration of thiamine

Thiamine should be given initially by the intravenous or intramuscular route, in order to obtain the maximal results. This may be followed by the oral administration of a maintenance dose. The daily dose of 100 mg is probably excessive, however, since unfavorable results have never been observed even with massive doses (Weiss et al), this dosage seems justified, particularly in view of the fact that it is difficult to judge the requirements of individual patients

The use of other components of the vitamin B complex has been advocated since associated vitamin deficiencies often occur. However, in the initial stages, the authors prefer the administration of thiamine alone in order to observe its specific effects, adding the other vitamin fractions later if necessary. Obviously, the control of chronic alcoholism and the correction of the dietary deficiencies should be carefully completed, and full instructions given to the patients Unfortunately, however, they often tend to revert to their previous habits, once they have obtained considerable relief from the signs and symptoms of beriberi heart disease

CIRCULATION TIME IN BERIBERI AND IN ANEMIA

BERIBERI HEART DISEASE

The cardiovascular dynamics of beriberi have their origin in the peripheral vascular system and consequently resemble the mechanisms encountered in anemia, hyperthyroidism, ar-

and to consequent peripheral vasodilatation The abnormal peripheral *circulation is due* to deficiency of thiamine and to *faulty oxidative* mechanisms mediated through the enzyme cocarboxylase There is also some experimental evidence that the lack of thiamine has a direct action upon the myocardium as well as upon the periphery. In such cases, *the circulation* time becomes accelerated as the peripheral resistance becomes diminished through the multiple arteriovenous shunts As in *other* conditions associated with an abbreviated circulation *time*, beriberi heart is characterized by an increase in the venous return *as well* as by an increase in the cardiac *output* According to various investigators, the circulation time is not increased in all cases Keefer found it increased in only about one-third of the cases he observed in China. *Blankenhorn* et al stressed that, in the Western type of beriberi, the acceleration of circulation time is rare According to the literature, when heart failure supervenes in beriberi heart, the data relating to circulation times may be obscured, not *only by heart failure*, but also by mental cloudiness, which renders accurate evaluation more difficult

ANEMIA

Since the pioneer observations of Blumgart et al with radium C, it has been known that circulation time is reduced in both primary and secondary anemias and that the increase in circulation speed parallels the severity of *the anemia*. In a general way, it has been found that a reduction in hemoglobin between 6 and 8 Gm will give circulation time measurements which are comparable to those obtained in arteriovenous fistula, hyperthyroidism, beriberi, pregnancy, and febrile states. Although the circulation speed does not become noticeably altered until the hemoglobin falls to a level of *less* than 8 Gm, reductions in hemoglobin below 6 Gm have pronounced *effects* in accelerating blood flow. *In such* cases, it has not been unusual to obtain an "arm-to-tongue" time of 6 *sec*. Apparently the quantity of blood reaching the tissues may be doubled or more by *virtue* of an accelerated blood flow which a *priori* increases the cardiac output In this way, the body tissues can withdraw as much *oxygen* per unit of time as they would if the hemoglobin content *of the blood*

From the *pathogenic standpoint,* Aalsmeer and Wenckebach believe that a metabolic disturbance resulting from thiamine deficiency causes fluid retention leading to edema of the striated muscles, including the myocardium itself, and decreasing cardiac contractility. According to them, there is no hypertrophy of the heart in beriberi, but rather an increase in thickness of the ventricular walls due to edema of the myocardium. Notwithstanding the diffuse involvement of the heart, they observed an initial and predominant right heart failure and the early occurrence of tricuspid insufficiency due to right ventricular distention. Several cases exhibit peripheral arteriolar dilatation, partly attributed to vasomotor paralysis and partly to acidosis, as a result of accumulation of lactic acid in the blood, a finding which becomes more marked on exertion (Inawashiro et al). In view of this hemodynamic disturbance, there is an overload of the right ventricle which is already involved by the above factors.

Although the exact mechanism of heart failure in beriberi is not entirely understood, the available evidence points to the combined result of myocardial damage and peripheral dilatation, leading to a peculiar combination of an overactive circulation and a failing heart.

The importance of the vascular factor was emphasized by Wenckebach, who described the vascular syndrome of Oriental beriberi Youmans and Huckins attributed the early cardiovascular changes to a "chronic venous congestion without heart failure." This syndrome is characterized essentially by hypervolemia with increased venous pressure and other congestive manifestations, due to a diffuse vasodilatation, increased venous return, and elevated cardiac output.

Since the arteriolar changes are less marked in the kidneys, there is a relative renal ischemia, which presumably persists until it is neutralized by the increase in cardiac output. According to these authors, it is possible that the renal factor may be involved in the mechanisms which lead to hypervolemia. These hemodynamic changes become more marked and persistent, resulting eventually in cardiac strain by stretching the myocardial fibers to a point which interferes with their adequate contractility, this is the main cause of heart failure with a decrease in cardiac output, as compared to its previously normal levels. According to these studies, it is important from the therapeutic standpoint to distinguish the hemodynamic phase from the myocardial stage of beriberi heart disease. Digitalis is not recommended in the former while it may be useful in the latter.

The importance of the vascular factor is recognized by most authors, such as Weiss and Wilkins (1937a). The authors believe that it is not as important as it has been claimed in the Orient, since they have observed the hyperkinetic syndrome in less than 50 per cent of their own cases. They believe that, in most cases, the myocardial lesion was mainly responsible for the cardiovascular changes and represented the sole factor leading to heart failure.

Thus, two factors are involved in variable degrees in the pathogenesis of heart failure in beriberi. For some unknown reason, the peripheral vascular changes predominate in the Orient, whereas the myocardial factor is more important in the Occidental form of cardiac beriberi.

In summary, thiamine deficiency results from the disproportion between the ingestion of vitamin B_1 and the caloric content of the diet, it leads to a disturbance of the intermediary metabolism of carbohydrates with an increase in the blood levels of lactic and pyruvic acids affecting the heart muscle. A certain degree of peripheral vascular dilatation which results from either an accumulation of the acid metabolites or a degenerative process of the perivascular nerve endings, leads to an increase in venous return. The combined effect, of cardiac overload and myocardial involvement, culminates in the clinical picture of high output failure.

Therapy. The administration of thiamine is obviously the basis of therapy. A dramatic improvement of heart failure often occurs in advanced cases which do not respond satisfactorily to cardiac glycosides. In view of these results, the therapeutic test with thiamine has been included as one of the important diagnostic criteria in beriberi heart disease. Although of great value, it should be emphasized that it may occasionally fail in the severe and irreversible forms of the disease, while digitalis and diuretics may induce remarkable improvement

Cardiac Catheterization in Subendocardial Fibroelastosis and Constrictive Diseases

JOSHUA LYNFIELD AND BENJAMIN CASUL

PATHOLOGICAL ASPECTS

Fibrotic thickening of the endocardium is seen in a variety of conditions It is a very marked feature in endocardial fibroelastosis, which is known to affect adults as well as children Fibrosis of the endocardium is often found over old areas of myocardial damage, as in ischemic heart disease, or in areas contiguous to valves which are the sites of rheumatic or arteriosclerotic changes, it is also found in areas where blood eddies or abnormally directed blood streams impinge on the endocardial surface and cause the so-called *Zahn-Schmincke pockets to develop* Endocardial fibrosis is a feature of certain types of congenital heart disease and is especially marked in the left ventricle of those patients in whom the left coronary artery arises from the pulmonary artery Apart from these well-defined conditions, there are many reports of patients who have died with intractable heart disease and who have been found at autopsy to have varying degrees of endocardial fibrosis, multiple mural thrombi, or both These have been recorded, either as isolated cases or as small groups from most European countries and from North America over a period of many years The origin of these cases remains obscure, the pathogenesis uncertain, and the classification unsatisfactory. This is reflected in the profusion of names applied to these conditions: subacute, isolated, idiopathic, or pernicious myocarditis; parietal endocardial sclerosis, cardiovascular collagenosis; nutritional heart disease; Occidental beriberi, chronic parietal endocarditis of nonvalvular origin, recurrent parietal thromboendocarditis, endocarditis parietalis fibroplastica, and so on One condition has been more clearly defined, namely, *Löffler's disease* or *endocarditis parietalis fibroplastica* in which there is usually a marked blood eosinophilia, which may or may not persist until death Apart from the eosinophilia, other evidence of allergic states has been found in a number of cases described under this name, and in some patients a definite valvulitis has been seen.

In recent years many cases of heart failure with endocardial fibrosis have been found in different parts of Africa and it is now clearly recognized as a major cause of heart disease in Africans in several areas of Africa. The frequency of this disease was first recognized in African troops in Egypt in World War II. The high incidence in Uganda was first realized in 1946, and subsequent reports have shown that it exists in the Sudan, Belgian Congo, Nigeria, Ghana, and in Gambia, as well as in Central Africa. It seems to occur less rarely in South

were normal, a fact corroborated by plethysmographic studies which reveal that the quantitative increase of blood flow through peripheral tissues in the presence of anemia is considerable.

Peripheral mechanisms operate to increase the circulation speed in chronic anemia. The impoverished blood leads to tissue *hypoxia* which results in the accumulation of acid metabolites. The direct or reflex action of the latter is responsible for peripheral vasodilatation. A more rapid venous return to the heart ensues, through a mechanism which is strongly *suggestive of the presence of multiple peripheral venous shunts*. There also is an additional factor of diminished viscosity engendered through the presence of a low red-blood-cell count.

When heart failure complicates *severe chronic anemia*, it fails to produce the characteristic prolongation of circulation time. If it is pure anemic heart failure with a very low hemoglobin content, the circulation time may, in fact, be within the normal range. This is due to the fact that, although congestive heart failure causes slowing of the circulation speed, the retardation is in part neutralized by the diminished blood viscosity in anemia, by the increased cardiac output, and by peripheral *vasodilatation*. Thus, circulation time reading will depend, not only upon the degree of heart failure, but also upon the degree of anemia.

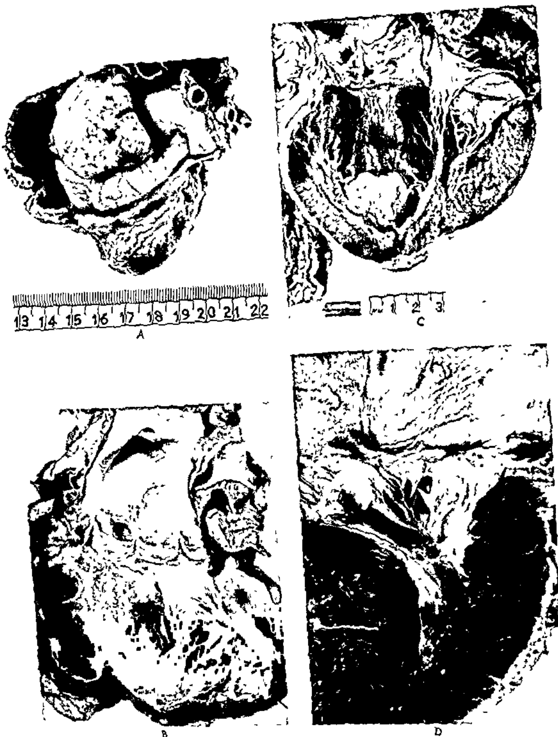

Fig. 16-25. Upper left: external view of heart of a case of endomyocardial fibrosis with lesions in the right ventricle, showing the external depression. Upper right: Left ventricle in a case of endomyocardial fibrosis showing noninvolvement of the endocardial tissue below the aortic valve and mitral valves. Lower left: Left ventricle in a case of endomyocardial fibrosis showing involvement of the myocardium of the apex and inflow tract extending behind the mitral valve. Lower right: Involvement of the mitral valve, which is being bound down to the mural endocardium, in a case of endomyocardial fibrosis.

Africa. There are indications that it occurs in India, Oceania, and Malaya, as well as in the West Indies and South America.

The name *endomyocardial fibrosis* has been given to this condition, first to emphasize the dual involvement of the endocardium and the myocardium, second because it was at first found only in Africa, and third because the lesions appeared, and still appear, to differ in many respects from those reported in the conditions previously mentioned. Thick irregular plaques of fibrous tissue cover parts of the endocardial surfaces of the cardiac ventricles and atria. The ventricular endocardium of the inflow tract and apex are particularly affected, and the atrioventricular valves are frequently involved in the fibrotic process, although the latter never involves the semilunar valves. Mural thrombi are often superimposed on the fibrous tissue, and strands of fibrous tissue invariably extend deeply into the myocardium Elastosis is not a feature of this condition.

Incidence. In Southern Uganda, recently, endomyocardial fibrosis has been the form of heart disease most frequently diagnosed in African patients (21 per cent of cases with heart disease). This is of course in a population in which coronary heart disease, thyrotoxic heart failure, and pulmonary heart disease are extremely rare, and in which subacute bacterial endocarditis, severe atheromatosis, and malignant hypertension are uncommon. On the other hand, infectious forms of heart disease and hypertension secondary to renal disease are common The clinical evidence is supported by autopsy data which showed that endomyocardial fibrosis was found in 33 instances, out of 231 autopsies on patients dying of heart disease. It affects both sexes equally and occurs at all ages, from 40 months to over 70 years.

Pathological Changes. The affected heart may vary from *hypertrophic* to *grossly atrophic,* weights of from 120 to over 600 Gm having been recorded in African adults The normal heart weight of the Uganda African is 0 58 per cent of the body weight but, since the body weights of Africans are considerably lower than those of European adults, the heart weights in absolute figures tend to be lower. Allowing for this, *cardiac hypertrophy* is found in about 60 per cent of cases. Large *pericardial effusions* are sometimes seen Externally, the heart often shows a rugose wrinkled appearance of the epicardium, particularly towards the apex. Over *the apex of the right ventricle,* there may be a deeply depressed, puckered area forming a saucerlike or wedge-shaped depression (Fig 16-25A). Occasionally such a depression is seen above the apex (small-waisted right ventricle). These external depressions are not seen over the left ventricular apex; when seen over the right apex, they indicate that a severe lesion is present in the right ventricle. About half of the cases of endomyocardial fibrosis show these depressions and in some instances there is an accompanying dilatation of the pulmonary conus.

Internally, the endocardium of the ventricles shows the most constant and severe lesions While only one ventricle may be affected (Fig. 16-25B), in the majority of cases lesions are present in both, though the most extensive and severe lesions are usually found in the left ventricle. Lesions of the atria are present in about one-third to one-half of the cases, either in the form of an adherent ante mortem thrombus or of fibrosis of the endocardium, patchy or diffuse. The lesions of the ventricles follow a definite pattern. The apex of the ventricles is most commonly involved with the lesion extending only a short distance up the septal wall, usually for about one inch, and terminating in many cases in a thick ridge of fibrous tissue with a rolled edge Above this, in the left ventricle, the endocardium is invariably unaffected below the aortic valve (Fig. 16-25C). Spread of the lesions onto the anterior wall is usually restricted in a similar manner but, in striking contrast, the posterior walls are extensively involved, with thick masses of fibrous tissue extending upwards and reaching to the base of the posterior cusps of the atrioventricular valves. Thus, a thick layer of fibrous tissue often extends downwards, from behind the posterior cusps of the AV valves, over the whole of the posterior wall and over the whole apex of the left ventricle, to form a single sheet of fibrous tissue of a shape not unlike an old-fashioned wax-candle snuffer. To this sheet of fibrous tissue, which lies behind the posterior cusps, the valve cusp itself may become adherent together with the chordae tendineae and papillary muscles, so that the

the regions penetrated by the fibrous tissue strands is normal in gross appearance or may appear slightly engorged, but myocardial fibrosis not connected with the endocardial fibrosis is not seen No lesions have been noted in the coronary arteries or veins or in the cardiac nerves or lymphatics, and the epicardial and pericardial surfaces usually show no lesions, even though sizable pericardial effusions may be seen

In summary, the gross lesions of endomyocardial fibrosis consist of *apical and inflow tract endocardial fibrosis* with involvement of the inner parts of the myocardium, there is often a superimposed mural thrombus, sometimes calcification, and rarely a terminal bacterial endocarditis. Fibrosis with thrombus formation occurs in the atria The posterior cusps of the atrioventricular valves are often bound down to the mural fibrous tissue and, in severe cases, the whole of the valvular apparatus may disappear The other AV valve cusps are less frequently involved and the semilunar valves are unaffected Associated congenital lesions are very rarely encountered.

Histological examination adds comparatively little to the knowledge gained by gross examination The fibrous tissue is compact and often hyalinized in the superficial areas and more loosely textured in the deeper layers where there are usually many thin-walled dilated blood vessels with a sprinkling of chronic inflammatory cells in which some pigmented macrophages may be seen Dilated blood vessels, all thin walled, are seen in the strands of fibrous tissue penetrating into the myocardium and these are presumably dilated thebesian veins and arterioluminal vessels There is usually no elastic fiber production and, where elastosis does occur, it is scanty and irregular. Calcification, where present, is seen in the more compact superficial layers of the fibrous tissue or in the affected valve cusps

The myocardium is constantly invaded by the strands of fibrous tissue in which are the blood lagoons, and these strands tend to surround small areas of myocardium in which a variety of degenerative changes may be observed In other areas, including those not covered by endocardial fibrosis, the myocardial fibers usually show degenerative changes Commonly these consist of a watery vacuolization or an interfibrillary edema, producing the aptly named *moth-eaten fibers* The nuclei are often large and hyperchromatic with square ends or may be shaped like long cigars Fatty infiltration is not seen. The changes are most marked in the subendocardial regions and diminish in intensity toward the deeper layers Cellular infiltration is always minimal; Aschoff bodies are not seen; and the only increased cellularity seen is in the layer of chronic inflammatory cells of the granulation tissue layer separating the fibrous tissue from the myocardial fibers. There has been no evidence of parasitic disease, and old or recent large scale necrosis of cells is not seen, save in some of the small areas surrounded by fibrous tissue Where the fibrotic lesions are advanced, there may be obliterative changes in some of the smaller arteries, but this is seen only in a minority of cases

No constant gross or microscopic changes are seen in organs or tissues other than the heart. Death is often from pneumonia or some other infective condition Examination has failed to reveal evidence of any generalized vascular disease or occlusive condition, or of any allergic lesions or generalized collagenous change. A puzzling feature is the existence of patients who show no evidence of cardiac disease in life but, after death from some unrelated disease, may show severe endomyocardial fibrosis It is thus evident that severe degrees of endomyocardial fibrosis may exist, particularly if the heart valves are not affected, without causing obvious embarrassment to the cardiac action Eosinophilia in the blood or in the tissues is not a feature of these cases and occurs only in a minority of instances.

CLINICOPATHOLOGICAL CORRELATIONS

The differences in the gross lesions found in hearts affected by endomyocardial fibrosis can be correlated with various clinical patterns which are encountered in patients with this disease There may be no clinical evidence of heart disease in some, as described above There may be evidence of failure of one or other or both ventricles with or without evidence of disease of the atrioventricular valves Some patients present evidence of constrictive heart disease. Where valvular disease exists, it usually takes the form of incompetence of the mitral, or, less commonly, the tricuspid valve. Stenosis of these valves may occur but

cusp itself disappears in a single sheet of irregular fibrous tissue extending from the atrium to the apex (Fig. 16-25D). The outlines of the engulfed chordae tendineae and the papillary muscles may be appreciated as irregular ridges in the sheet of fibrous tissue, and the outline of the cusp may be felt as a firm ridge.

While this is the basic type of lesion seen in advanced cases in the ventricles, in the right ventricle it is often modified by changes due to the peculiar configuration of this chamber. The spatial arrangements are such that, when the fibrous sheets form, the surfaces rapidly come into contact with each other and fuse. As a result, the whole apex is filled with fibrous tissue and thrombus, and the cavity of the apex is obliterated. When the cavity is filled at the apex, a section of the ventricle at right angles to the septal wall will disclose a triangular mass of clot and fibrous tissue. However, the fusion may take place at some distance above the apex, when this happens, the cavity below falls in, and a large triangular wedge of muscle is seen on sectioning at a right angle to the septal wall. In such instances, a small endocardium-lined crypt may be found in this wedge of muscle, indicating the original apical cavity of the right ventricle. However the obliteration of the right ventricle comes about, it is always manifested externally by the puckering and depressions over the right ventricle previously described, and the presence of such an external lesion is a sure indication of obliteration of the cavity. The effect of this obliteration is to move the effective apex of the right ventricle progressively nearer to the tricuspid valve while the available cavity of the right ventricle is reduced to a shallow saucer in which the fibrosed posterior papillary muscle frequently sticks up like a marble pillar In such cases, the pulmonary conus is usually dilated and hypertrophied and there may be some fibrosis of the endocardium. This, however, is always slight and always ends some distance below the pulmonary valve cusps Like the cusps of the aortic valve, the pulmonary cusps have not been affected, in over 100 cases of endomyocardial fibrosis examined However, some of the longest clinical histories of heart disease are given by patients who are found at autopsy to have right ventricular obliteration and a dilated conus with hypertrophied muscle.

Obliteration of the apex has not been found in the left ventricle, but the largest mural thrombi have been found in this chamber and they may take up the larger part of the cavity While the basic feature of this disease in both ventricles is the fibrosis, and this is usually located at the apex and on the posterior wall, other associated lesions may occur and the fibrosis may not be extensive It may be confined to the apex, to a region of the wall behind a papillary muscle or chorda, or to the region behind the posterior cusps without involving the apex. The muscle, chorda, or cusp may be fused to small areas of such fibrosis But where fibrosis occurs, it is at the apex or in the ventricular inflow tract and does not involve the outflow tracts below the semilunar valves.

The commonest associated lesion is superimposed *mural thrombosis*, which may vary from a brown-red or yellow-green discoloration of the usually pearly-white, glistening fibrous tissue to a massive intraventricular or atrial thrombus filling up most of the chamber. The largest thrombi are seen in the left ventricle. Occasionally, in either ventricle, a white spherical ball of fibrous tissue may be found at the apex which, on section, shows a dark central portion consisting of an old thrombus completely surrounded by fibrous tissue The more extensive the endocardial fibrosis, the greater the likelihood that there will be an overlying thrombus. A superimposed terminal *bacterial endocarditis* is sometimes seen *Calcification* of fibrous tissue is often seen varying from a few calcific specks to a large sheet of calcified endocardial tissue. This calcification is almost invariably seen in the superficial areas of the fibrous tissue, i.e., in the part nearest to the cavity. It is rarely found in the atria where large thrombi are not uncommon, particularly in the appendages

The fibrous tissue, particularly in the ventricles, may present a layered appearance with the denser white areas more superficially situated, while the deeper layers are darker in color and have strands of fibrous tissue extending from them deeply into the myocardium The fibrous tissue layer is often partly separated from the myocardium by a thin layer of engorged dilated blood vessels, and such dilated lagoons of blood may also be seen in the strands of fibrous tissue penetrating into the myocardium. The heart muscle beyond

tria, North America, and South Africa. Usually, in these instances, the hearts are enlarged and often very hypertrophied, in some, only single or multiple mural thrombi have been found, often giving rise to emboli, in others, there has been such extensive endocardial fibrosis that the term "constrictive endocarditis" has been used. Lesions similar to those termed "obliteration of the right ventricle" have been described. In those where there is marked endocardial fibrosis, the lesions are similar to those seen in endomyocardial fibrosis, though the extreme valvular conditions seen in the latter disease have rarely been reported, this may be because most reports deal with isolated cases or small groups of cases. If they are in fact identical, the geographical distribution of endomyocardial fibrosis is far wider than the African continent

At the same time there remains the problem that, outside tropical Africa, heart failure with mural thrombosis and resulting embolization is much more frequently reported than is endocardial fibrosis, whereas in tropical Africa the opposite obtains In areas where there is much coronary artery disease, endocardial fibrosis might be attributed to this rather than to some other form of heart disease But this is not true of South Africa where, in Africans, coronary artery disease is rare, heart failure with mural thrombosis and embolization is common, but endocardial fibrosis and valve involvement are rare In Uganda this is not so, and advanced fibrosis with valve involvement, without past or present embolization, is a common finding. If the lesions, thrombus-fibrosis, have a sequential relationship this is difficult to understand Where a late fibrotic state is common, one might expect to see many cases exhibiting mural thrombosis only or with partial fibrosis

Yet it is difficult to believe that the lesions of endomyocardial fibrosis could have arisen by any mechanism other than by the organization of mural thrombi, and the histological evidence does suggest that this has been the mechanism There is no evidence of any marked loss of myocardial tissue. However, providing that the formation of mural thrombi is an early lesion in endomyocardial fibrosis, then it must be either minimal or else it is speedily organized or covered by endothelium, for embolic lesions are rarely seen. If small in extent, the clot is presumably organized to produce the small fibrous plaques seen in some patients who have died without showing evidence of heart disease. If extensive, such thrombi must interfere with the endocardial-myocardial circulation, and this may in turn accentuate cardiac damage until the cardiac action is affected. Fresh thrombi may be deposited upon the old organized thrombi in the terminal stages of the disease and, because of the feebleness of the heart's action, may not be dislodged.

If this is the true pathogenesis of endomyocardial fibrosis, the initial cause of the cardiac damage and of the formation of mural thrombi remains quite obscure So far, no specific etiological evidence has been produced. It does not appear that any similar condition has been described in animals either spontaneously or under experimental conditions. An "aura" of malnutrition hangs over many cases of obscure heart disease in Africa and in other continents. But some patients have been well nourished while others have been recorded as visiting the tropics, which raises suspicion of an infective factor On the other hand, others have not been in the tropics Thus, the origin of endomyocardial fibrosis is obscure and will remain so for some time

On both clinical and pathological grounds, endomyocardial fibrosis appears to be a distinct entity, it is a major cause of heart disease in certain parts of Africa, it probably occurs in other continents, and the unraveling of its causes and pathogenesis may throw light on other forms of cardiac disease of obscure origin.

CLINICAL ASPECTS

The following account is based on clinical experience in East Africa, usually restricted to the late or terminal phases of the disorder The author does not know under what circumstances the earliest initial endocardial injury occurs, nor what clinical manifestations (if any) may accompany it and might enable a clinical diagnosis to be made at that early stage, if he were aware of them and knew exactly what to look for. Thus, the early his-

is a much more uncommon lesion. Thrombi in some of the cardiac chambers may reach such a size as to embarrass the heart, while the evidence of a terminal *bacterial endocarditis* may dominate the clinical picture. However, in the absence of such an endocarditis, it is remarkable how rarely there is either clinical or autopsy evidence of embolization from either side of the heart. This is in most striking contrast to the findings in other obscure forms of heart disease in which mural thrombosis is encountered.

RECOGNITION OF ENDOMYOCARDIAL FIBROSIS AND DISTINCTION FROM OTHER CONDITIONS

Two common conditions bear some resemblance to endomyocardial fibrosis. rheumatic heart disease and endocardial fibroelastosis. The late stages of rheumatic heart disease in Africans do not differ to any extent from the lesions seen in other races. Confusion with endomyocardial fibrosis can only arise where the lesions of this disease are confined to mural fibrosis adjacent to the atrioventricular valves. Points of distinction are (1) that the disease process in rheumatic heart disease, if the mural endocardium in the ventricle is affected at all, spreads from the valve, which is the most affected part, to the wall which is the least affected, (2) whereas in endomyocardial fibrosis the wall is most affected and the process spreads to the valve, the posterior cusp is most affected and the anterior cusps least affected, while the semilunar valves are not affected in endomyocardial fibrosis and, microscopically, rheumatic myocardial lesions are not found It is of course possible that both diseases are present in the same patient.

Distinction from endocardial fibroelastosis is usually easy and is confirmed by microscopy which reveals little or no elastosis in cases of endomyocardial fibrosis. Fibroelastosis is usually found in young children, though it does occur rarely in adults, the lesions are usually more clearly confined to the endocardium without any particular localization to the inflow tract, indeed involvement of the endocardium below the aortic valve is commonly seen The degree of endocardial thickening is rarely great and obliteration of the right ventricle does not seem to have been described. Other lesions of congenital nature are common and the semilunar valves are often involved In these respects fibroelastosis differs from endomyocardial fibrosis and when, in fibroelastosis, the atrioventricular valves are affected, they are not usually bound down to and engulfed in the mural endocardium as they are in endomyocardial fibrosis. Consideration of these points enables a distinction to be made between these conditions by gross examination, and this can be confirmed by histological examination. The lesions seen in ischemic heart disease, scleroderma, and diffuse lupus erythematosus clearly bear little resemblance to the lesions seen in endomyocardial fibrosis

ENDOMYOCARDIAL FIBROSIS AND OTHER OBSCURE FORMS OF CARDIAC DISEASE

As a specific entity, endomyocardial fibrosis has been described and characterized in Africans; in this disease the hearts may be atrophied or hypertrophied and embolic phenomena are distinctly rare. On the other hand, there are numerous reports from other continents and indeed from Africa as well, of patients with obscure forms of heart disease in which the hearts are usually hypertrophied, mural thrombosis is marked, and embolic phenomena are prominent and may dominate the clinical picture. In some of these cases, eosinophilia may be pronounced but endocardial fibrosis is often absent or minimal Such disorders have occurred in Europeans in West Africa, an area in which endomyocardial fibrosis is known to occur The clinical picture was one of obscure heart failure; there was a large heart with multiple embolic lesions and pronounced eosinophilia; the patients were well nourished, although they may have had a parasitic infestation capable of causing the eosinophilia. To this extent they differ from cases of Löffler's disease in which the eosinophilia is not due to a parasite but seems to be due to an allergic state, and widespread vascular disease due to allergy has been described in Löffler's disease. However such lesions have not been seen in endomyocardial fibrosis, in which no evidence of allergy has been found and eosinophilia is not common. Nor have allergic lesions or eosinophilia been marked in other cases of obscure heart disease with endocardial fibrosis or mural thrombi which have been recorded from France, Aus-

rior), an appearance accentuated where the aorta is small (Fig 16-27). In the right oblique view, a barium swallow will often outline an enlarged left atrium, though seldom to the extent seen in tight mitral stenosis, on the other hand, though the evidence of static left atrial enlargement is likely to be less than in stenosis, a *dynamic enlargement* with vigorous systolic expansion of the atrium in the oblique or posteroanterior views is sometimes striking This is important suggestive evidence of free organic regurgitation, though it is known that it is not pathognomonic and that it is sometimes absent in cases with typical mitral incompetence

Electrocardiographic evidence of atrial enlargement, namely, a disproportionately large P wave, or a lengthened P-R interval in the absence of mitral stenosis or pulmonary heart disease, are other suggestive findings

Thus the patient with endomyocardial mitral incompetence somewhat resembles the patient with rheumatic mitral disease in failure However, there is no opening snap, no diastolic or presystolic murmur, and no loud 1st sound, as in mitral stenosis, there is, on the contrary, a loud systolic murmur (and thrill), and a large left ventricle

Rheumatic mitral stenosis with severe incompetence, when the systolic murmur may have a harsh or squeaky quality, or with bacterial endocarditis, will be more difficult to distinguish When the diastolic murmur disappears, as it may do terminally in severe heart failure from mitral stenosis (Gorlin, 1954) or with the onset of atrial fibrillation, the distinction may be impossible clinically, though the history will usually be longer and fibrillation more likely in rheumatic disease

A *systolic murmur at the apex* is one of the most common of all physical signs, and is no evidence by itself of mitral incompetence, let alone of endomyocardial disease But when this is a loud murmur in a large, failing heart, there will usually be features of etiological significance· bacterial endocarditis, rheumatic or congenital disease, hypertension, severe anemia, thyrotoxicosis. When these can be excluded, and when there is the combination of a large left atrium and a large left ventricle, a large P wave, and a murmur of peculiar harshness and pitch, then endomyocardial mitral incompetence has to be considered, especially in a part of the world where endomyocardial disease is known to occur.

Fig. 16-27. Roentgenogram of patient with severe mitral incompetence due to endomyocardial fibrosis of left ventricle

TRICUSPID INSUFFICIENCY

Tricuspid incompetence as an isolated lesion with clear-cut physical signs is less common Endomyocardial disease of the right ventricle, extensive enough to involve the tricuspid, is likely to produce its characteristic obliterative features, thus obscuring the pure tricuspid signs Occasionally, however, cases of endomyocardial disease are seen which present tricuspid incompetence and the picture of right heart failure. Jugular vein engorgement and pulsation are present with prominent systolic pulsations, great hepatic enlargement, gross ascites, and edema. Expansile pulsation of the enlarged liver is to be expected but is not a constant finding. A systolic murmur may be heard at the lower end of the sternum

A large, globular heart shadow is seen on fluoroscopy without special enlargement of the left atrium or ventricle. Vigorous pulsation (systolic expansion) of the superior vena cava and right atrium may be observed but is not likely to be marked in the presence of extensive obliterative fibrosis of the right ventricle.

OBLITERATIVE FIBROSIS OF RIGHT VENTRICLE

Clinically severe right ventricular fibrosis resembles constrictive pericarditis more than anything else (Fienberg and Holzman, 1951). There is a greatly reduced diastolic filling of

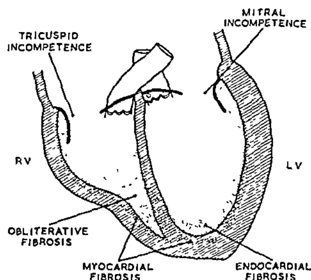

Fig. 16-26. Endomyocardial fibrosis. Distribution of lesions, valvular, endocardial, and myocardial, which may occur separately or in combination.

tory of the illness is not known. No association with previous cardiovascular, rheumatic, allergic, or pyrexial episodes has been observed, nor any constant association with previous infection, severe anemia, avitaminosis, or other nutritional deficiency. This is not unlike the situation of chronic mitral disease in the past, the condition was familiar to pathologists and clinicians but was not yet recognized to be the result of rheumatic fever. In its later stages, strikingly different clinical pictures are presented in rheumatic heart disease; pure mitral stenosis, isolated aortic incompetence, tricuspid stenosis, or the occurrence of two of them together may modify their distinctive clinical manifestations, as may the existence of a considerable degree of incompetence in a case of mitral stenosis In the same way, the clinical features of a particular case of endomyocardial fibrosis are determined by the site of the major endocardial lesion (Fig. 16-26) This may be confined to the left or right ventricle or may involve both, it may also grossly affect either mitral or tricuspid valve function, or both valves together, or neither, all of this resulting from an entirely similar pathology, the clinical signs depending upon its location in the heart or the site of its maximum severity.

One may encounter a number of sharply distinctive clinical patterns (Ball et al , 1954) in the late stages of endomyocardial fibrosis as well as some overlapping and much less distinctive patterns. These are: mitral insufficiency, tricuspid insufficiency, right ventricle obliterative fibrosis, combination of any of the above lesions, or heart failure without evidence of any of the above lesions

Bacterial endocarditis may be added to any of these. Also, but surprisingly seldom in the author's experience, single or repeated embolic episodes may occur with or without additional infection. Aortic or pulmonary signs are not encountered in endomyocardial fibrosis

The clinical lesions diagnosed in 24 cases in which endomyocardial fibrosis was confirmed at autopsy are given in Table 16-3

MITRAL INSUFFICIENCY

The first symptom is usually *shortness of breath,* sometimes with paroxysmal nocturnal dyspnea. But right-sided failure often supervenes quickly, so that edema and venous engorgement are usually present when the patient is first seen. The heart is enlarged and may suggest obvious left ventricle hypertrophy with a heaving apical impulse, or may be dilated and inert. There is *a loud systolic murmur* at the apex, often of a remarkably high pitch and with a harsh, dry, or squeaking quality. There may be a systolic thrill. There is no diastolic murmur.

Radiography may reveal no more than a diffuse enlargement of the heart, especially when pleural effusion obscures the picture. If the right heart is much enlarged, there may be close resemblance, in the posteroanterior view, to the squarish shadow commonly referred to as "mitralization" and associated with rheumatic mitral stenosis But when the left ventricle is much enlarged, as it often is in endomyocardial disease and especially in those cases with mitral incompetence, *this* will modify the squareness of the left border and give a more triangular shadow (posteroante-

not always tally with the appearance or weight of the heart at autopsy. This anomaly can arise from great dilatation of one or both atria or of the pulmonary outflow tract which contribute to the size of the cardiac shadow out of proportion to what they add to the weight of the organ or to its size when they are emptied of blood after death. Again, recalling the rigid fibrotic or calcified plaques, of considerable extent in some hearts, one cannot be surprised if enlargement takes place in a somewhat bizarre fashion, the ability of a chamber to dilate must vary markedly from one part of its wall to another and the radiographic appearance predicted for a particular lesion may not occur On fluoroscopy, lack of detectable pulsations is common and can be very deceptive This appearance is more often to be explained by gross dilatation than by effusion Paracentesis may be needed in order to exclude tuberculous pericarditis. The detection of calcification, if constrictive pericarditis were excluded, would be a very suggestive finding. This has not so far been observed in the course of clinical radiography, but the appearance in a post-mortem roentgenogram of the isolated heart (Fig. 16-28) indicates what may be expected

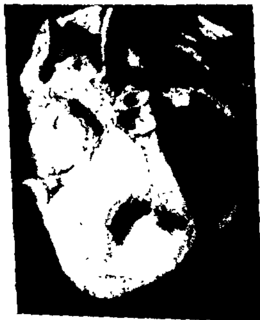

Fig. 16-28. Endocardial calcification in right ventricle radiographic appearance of the *isolated* autopsy specimen.

TABLE 16-4. INCIDENCE OF ABNORMAL ELECTROCARDIOGRAPHIC FINDINGS IN 24 CASES OF ENDOMYOCARDIAL FIBROSIS

ECG finding		*No of cases*
QRS less than 0 5 mv in limb leads		12
P exceeding 0.20 mv, or 0 11 sec		13
Atrial extrasystole		2
Atrial fibrillation		1
P-R exceeding 0 20 sec		6

Left ventricle hypertrophy	1	
Right bundle branch block	0	
Incomplete right branch block	2	5
Right ventricle hypertrophy	3	
Ventricular extrasystole		2
S-T deviation, without digitalis		0

Abnormal cardiograms are frequently present in the late stages of endomyocardial disease These may show evidence of atrial hypertrophy or strain, atrial fibrillation occasionally occurs. There may be right or left ventricular hypertrophy. Minor degrees of conduction disturbances, such as lengthened P-R interval or incomplete bundle branch block may occur. Flat and inverted T waves are common but the Q- and T-wave changes of infarction and necrosis are not seen in endomyocardial fibrosis; nor is significant S-T deviation a feature in the late stages of the disease which have been studied Low-voltage curves are common Cardiographic findings in 24 cases are summarized in Table 16-4. Clinical diagnosis and autopsy findings in the same patients are given in Tables 16-3 and 16-5 respectively.

As with the physical signs in this disease, there is no uniform or diagnostic cardiographic pattern This is due to the great variety in situation and extent of the endocardial and myocardial lesions and of their effects in producing hypertrophy or dilatation of particular chambers, also, because the muscle affected is confined to an extremely narrow zone, is separated from the electrode (in all leads except aVR) by a much thicker zone of undamaged myocardium, and is not (in the late stage of the disease) undergoing active injury or necrosis; in the last two respects, this is the opposite of acute pericarditis

The lack of any early history has been stressed. There is no consistent association with disease of other organs or systems In East

the right ventricle. Here again, jugular venous pressure, hepatic enlargement, and ascites are disproportionate to the symptoms. Tricuspid incompetence is absent or is overshadowed by the gross ventricular lesion; there is, therefore, no pulsation of the cervical veins or liver, and no tricuspid systolic murmur.

Roentgenology fails to supply characteristic data. There is no systolic expansion of the right atrium or superior vena cava. The right atrium and pulmonary outflow tract, however, may be severely dilated. Thus, a large shadow may serve to distinguish from constrictive pericarditis, but may be less easy to distinguish from earlier tuberculous pericarditis with effusion or with severe caseous and edematous thickening of the pericardium. Furthermore, endomyocardial disease may be accompanied by pericardial effusion. A classical feature of constrictive pericarditis, namely, calcification of the pericardium, is absent in endomyocardial disease. On the other hand, there is often considerable endocardial calcification; the possibility of this being mistaken for pericardial calcification on fluoroscopy or in the x-ray film should be kept in mind (Fig. 16-27).

Those patients with predominantly right ventricular endomyocardial disease may have signs out of proportion to their symptoms, and be relatively unembarrassed and have longer histories and survival than those with involvement of the left ventricle or both ventricles. Nonparoxysmal dyspnea, however, is sometimes present; this may be from several or from a combination of causes: pleural or pericardial effusion, or impeded diaphragmatic breathing due to ascites and liver enlargement.

COMBINED ENDOMYOCARDIAL LESIONS

Endomyocardial disease usually involves both ventricles with or without one or both atrioventricular valves. Thus, patients presenting one of the distinctive clinical patterns described above are a minority. The variety of possible, and actual, combinations, and the intergrading of clinical patterns which they produce, is considerable and complicates clinical diagnosis.

One possible variety is represented by a moderate degree of mitral stenosis, occasionally complicating incompetence of this valve, very rarely to an extent sufficient to produce a diastolic murmur. Tricuspid and mitral insufficiency is a common combination. Obliterative fibrosis of the right ventricle may occur with tricuspid or mitral incompetence or both. The association of predominantly right or left ventricular failure with tricuspid or mitral involvement is not consistent.

It is not surprising that a cardiac disorder producing such a variety of anatomical deformities and functional disturbances (more often in combination than separately) should have escaped recognition as a clinical entity for such a long time and should often still defy diagnosis during life.

HEART FAILURE WITHOUT VALVULAR OR OBLITERATIVE LESIONS

The harmful effects of endomyocardial fibrosis are not confined to the valves. Extensive involvement of the wall of the ventricle is possible without affecting the AV valves and without gross obliterative effect, particularly in the left ventricle. Such cases present heart failure without special features. The heart is enlarged; there may be a soft systolic murmur at the apex or no murmur. It may be clear from the history that exertional dyspnea has preceded other symptoms, suggesting initial left ventricular failure; this, however, fails to give a clue to the pathologic changes, except that the absence of hypertension and of coronary or aortic disease may give a lead. In other cases, heart failure develops without indicating predominant involvement of one side more than the other.

DIAGNOSTIC CONSIDERATIONS

All too often, diagnosis can only follow a careful exclusion of the better-known possible causes for the signs and symptoms, considered in relation to the local incidence of heart diseases where the patient lives or has traveled. A diagnosis of endomyocardial fibrosis will not be made lightly in a country where many autopsies are performed and yet endomyocardial fibrosis is never seen. Unfortunately, neither radiography nor electrocardiography are of more than limited value, for reasons which will be discussed below.

Radiographic and Fluoroscopic Findings. These findings, in cases of pure mitral and tricuspid incompetence, may be characteristic. In general, the radiographic appearance does

not always tally with the appearance or weight of the heart at autopsy. This anomaly can arise from great dilatation of one or both atria or of the pulmonary outflow tract which contribute to the size of the cardiac shadow out of proportion to what they add to the weight of the organ or to its size when they are emptied of blood after death Again, recalling the rigid fibrotic or calcified plaques, of considerable extent in some hearts, one cannot be surprised if enlargement takes place in a somewhat bizarre fashion, the ability of a chamber to dilate must vary markedly from one part of its wall to another and the radiographic appearance predicted for a particular lesion may not occur. On fluoroscopy, lack of detectable pulsations is common and can be very deceptive. This appearance is more often to be explained by gross dilatation than by effusion Paracentesis may be needed in order to exclude tuberculous pericarditis The detection of calcification, if constrictive pericarditis were excluded, would be a very suggestive finding This has not so far been observed in the course of clinical radiography, but the appearance in a post-mortem roentgenogram of the isolated heart (Fig 16-28) indicates what may be expected

Fig 16-28. Endocardial calcification in right ventricle, radiographic appearance of the isolated autopsy specimen.

TABLE 16-4. INCIDENCE OF ABNORMAL ELECTROCARDIOGRAPHIC FINDINGS IN 24 CASES OF ENDOMYOCARDIAL FIBROSIS

ECG finding		*No. of cases*

Abnormal cardiograms are frequently present in the late stages of endomyocardial disease These may show evidence of atrial hypertrophy or strain, atrial fibrillation occasionally occurs. There may be right or left ventricular hypertrophy Minor degrees of conduction disturbances, such as lengthened P-R interval or incomplete bundle branch block may occur. Flat and inverted T waves are common but the Q- and T-wave changes of infarction and necrosis are not seen in endomyocardial fibrosis, nor is significant S-T deviation a feature in the late stages of the disease which have been studied Low-voltage curves are common. Cardiographic findings in 24 cases are summarized in Table 16-4 Clinical diagnosis and autopsy findings in the same patients are given in Tables 16-3 and 16-5 respectively

As with the physical signs in this disease, there is no uniform or diagnostic cardiographic pattern This is due to the great variety in situation and extent of the endocardial and myocardial lesions and of their effects in producing hypertrophy or dilatation of particular chambers, also, because the muscle affected is confined to an extremely narrow zone, is separated from the electrode (in all leads except aVR) by a much thicker zone of undamaged myocardium, and is not (in the late stage of the disease) undergoing active injury or necrosis; in the last two respects, this is the opposite of acute pericarditis

The lack of any early history has been stressed There is no consistent association with disease of other organs or systems. In East

the right ventricle. Here again, jugular venous pressure, hepatic enlargement, and ascites are disproportionate to the symptoms. Tricuspid incompetence is absent or is overshadowed by the gross ventricular lesion; there is, therefore, no pulsation of the cervical veins or liver, and no tricuspid systolic murmur.

Roentgenology fails to supply characteristic data. There is no systolic expansion of the right atrium or superior vena cava. The right atrium and pulmonary outflow tract, however, may be severely dilated. Thus, a large shadow may serve to distinguish from constrictive pericarditis, but may be less easy to distinguish from earlier tuberculous pericarditis with effusion or with severe caseous and edematous thickening of the pericardium. Furthermore, endomyocardial disease may be accompanied by *pericardial effusion.* A classical feature of constrictive pericarditis, namely, calcification of the pericardium, is absent in endomyocardial disease. On the other hand, there is often considerable *endocardial calcification,* the possibility of this being mistaken for pericardial calcification on fluoroscopy or in the x-ray film should be kept in mind (Fig. 16-27).

Those patients with predominantly right ventricular endomyocardial disease may have signs out of proportion to their symptoms, and be relatively unembarrassed and have longer histories and survival than those with involvement of the left ventricle or both ventricles. Nonparoxysmal dyspnea, however, is sometimes present, this may be from several or from a combination of causes pleural or pericardial effusion, or impeded diaphragmatic breathing due to ascites and liver enlargement.

COMBINED ENDOMYOCARDIAL LESIONS

Endomyocardial disease usually involves both ventricles with or without one or both atrioventricular valves Thus, patients presenting one of the distinctive clinical patterns described above are a minority The variety of possible, and actual, combinations, and the intergrading of clinical patterns which they produce, is considerable and complicates clinical diagnosis.

One possible variety is represented by a moderate degree of *mitral stenosis,* occasionally complicating incompetence of this valve, very rarely to an extent sufficient to produce a diastolic murmur. *Tricuspid and mitral insufficiency* is a common combination. Obliterative fibrosis of the right ventricle may occur with tricuspid or mitral incompetence or both. The association of predominantly right or left ventricular failure with tricuspid or mitral involvement is not consistent

It is not surprising that a cardiac disorder producing such a variety of anatomical deformities and functional disturbances (more often in combination than separately) should have escaped recognition as a clinical entity for such a long time and should often still defy diagnosis during life.

HEART FAILURE WITHOUT VALVULAR OR OBLITERATIVE LESIONS

The harmful effects of endomyocardial fibrosis are not confined to the valves Extensive involvement of the wall of the ventricle is possible without affecting the AV valves and without gross obliterative effect, particularly in the left ventricle. Such cases present heart failure without special features The heart is enlarged; there may be a soft systolic murmur at the apex or no murmur It may be clear from the history that exertional dyspnea has preceded other symptoms, suggesting initial left ventricular failure; this, however, fails to give a clue to the pathologic changes, except that the absence of hypertension and of coronary or aortic disease may give a lead. In other cases, heart failure develops without indicating predominant involvement of one side more than the other.

DIAGNOSTIC CONSIDERATIONS

All too often, diagnosis can only follow a careful exclusion of the better-known possible causes for the signs and symptoms, considered in relation to the local incidence of heart diseases where the patient lives or has traveled A diagnosis of endomyocardial fibrosis will not be made lightly in a country where many autopsies are performed and yet endomyocardial fibrosis is never seen. Unfortunately, neither radiography nor electrocardiography are of more than limited value, for reasons which will be discussed below.

Radiographic and Fluoroscopic Findings. These findings, in cases of pure mitral and tricuspid incompetence, may be characteristic In general, the radiographic appearance does

may extend into the myocardium *Marked left ventricular hypertrophy* is almost always present and *right ventricular hypertrophy* is frequently seen Two types of subendocardial fibroelastosis may be recognized on the basis of the appearance of the left ventricle. the *dilated type* and the *contracted type*, the former is more common than the latter (Edwards). It is presumed that the thickened endocardium interferes with and limits the expansion and contraction of the ventricle from the inside in much the same way as does the scar tissue deposited around the heart in constrictive pericarditis (Thomas). Thus, this condition is sometimes called "constrictive endocardial sclerosis." Angiocardiographic findings may show small change in systolic and diastolic volume of the left ventricle (Gasul; Linde) It is important to recognize that fibroelastosis may be secondary to an obstructive lesion such as aortic or mitral stenosis, or secondary to anomalous origin of the left coronary artery from the pulmonary artery Such instances are not considered in the present discussion

A brief discussion of the conditions encountered in constrictive pericarditis is appropriate

HEMODYNAMICS OF CHRONIC CONSTRICTIVE PERICARDITIS

Hemodynamic studies of chronic constrictive pericarditis and related conditions have helped greatly in understanding the hemodynamic changes associated with subendocardial fibroelastosis The classical description of the pathophysiology of chronic constrictive pericarditis was given by Chevers over 100 years ago. He stated "The principal cause of dangerous *symptoms* appears to arise from the occurrence of gradual contraction in the layer of adhesive matter which has been deposited around the heart, compressing its muscular tissue, and embarrassing its systolic and diastolic movements, but more particularly the *latter*" Impairment of diastolic filling of the ventricles is characteristic of constrictive pericarditis but may occur in other conditions These include diffuse *myocardial fibrosis*, *endocardial fibrosis*, *primary amyloidosis of the heart*, and *pericardial effusion* (Clark). Cardiac catheterization in these conditions and in chronic constrictive pericarditis may reveal characteristic alterations in the pressures and flows Similar, but usually less marked changes, have also been observed in *congestive heart failure*. Chronic constrictive pericarditis usually involves the left and right ventricles to a similar degree. Most of the information which follows relating to this condition has been obtained by right heart catheterization However, left ventricular pulse pressures obtained at the time of surgery have been reported (Hansen). When constrictive pericarditis predominantly involves the left ventricle, right heart catheterization data show evidence of pulmonary hypertension, secondary to the elevated left ventricular diastolic pressure (White, 1948). Constriction of the atria is rarely, if ever, of primary importance in constrictive *pericarditis (Isaacs)*.

A serious consequence of impairment of diastolic filling is a *reduced stroke volume* and a *reduced cardiac output* An increase in the cardiac output on exercise is accomplished under these conditions *entirely by increasing* the heart rate The pressure pulse records usually show a marked elevation of the mean right atrial and right ventricular diastolic pres-

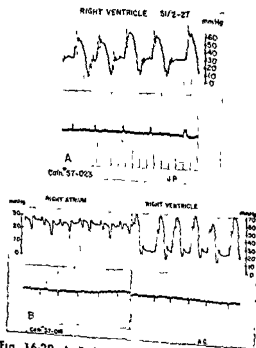

Fig. 16-29 A Right ventricular pressure-pulse tracing of a patient with a constricting band over the anterior part of the heart illustrating early-diastolic dip and plateau. B. African patients with endomyocardial fibrosis, considerable *splenomegaly* has been noted in some, and is absent in others, the same can be said of *eosinophilia*. *Embolism* from mural thrombi, pulmonary or systemic, may occur. It has been observed in East African patients with endomyocardial fibrosis less often then in similar cases (Gray, 1951) reported from other parts of the world.

Differential diagnosis requires consideration of rheumatic heart disease, tuberculous pericarditis, bacterial endocarditis, and congenital heart disease Severe anemia and liver cirrhosis (both of which may occur as complications) may also simulate endomyocardial fibrosis in certain features, as may nutritional heart disease (Gillanders, 1951), and the heart in chronic alcoholism and beriberi The clinical differentiation of endomyocardial fibrosis from the ill-defined group of myocardial disorders of unknown origin (isolated myocarditis and others) must often remain exceedingly difficult or impossible.

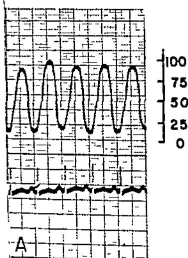
TREATMENT AND PROGNOSIS

Without knowledge of cause or pathogenesis and without a basis for early diagnosis, a rational therapy to arrest or reverse the condition before fibrosis has advanced to a damaging extent is not available. That the lesion can be self-arresting, and that even extensive fibrosis can be present without cardiovascular symptoms if valves and myocardium are not severely affected, is clear from autopsy findings of endomyocardial fibrosis unrelated to the cause of death If the author cannot yet say that this is a preventable disorder, he can at least infer that, if it could be detected and arrested at an early stage, satisfactory cardiac function could be preserved. A rationale for an early etiological treatment which would be effective in arresting the thrombofibrotic process is therefore much to be desired.

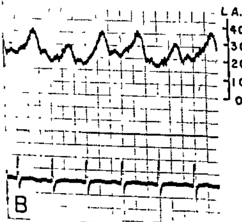
The late endocardial and valve lesions are *not* amenable to surgery. At this stage, the response of heart failure to *digitalis* and *mercurial diuretics* varies from patient to patient, some are able to resume sedentary ambulant activity for a few months, others remain bedridden with little or no improvement. Prognosis, once heart failure is established, is extremely poor. The majority do not survive beyond 1 or 2 years. The longest duration of symptoms has been recorded in patients with pure or predominant right ventricular lesions with or without tricuspid incompetence, two patients lived for 4 years and one for 8 years It is probable that survival is longest in cases of this kind, in whom both the pulmonary circulation and the left ventricle are protected from extremes of load

CARDIAC CATHETERIZATION IN SUBENDOCARDIAL FIBROELASTOSIS AND CONSTRICTIVE DISEASES [1]

SUBENDOCARDIAL FIBROELASTOSIS



This is a condition of unknown cause characterized by a diffuse thickening of the endocardium, associated with cardiac hypertrophy, and most frequently involving the left ventricle and left atrium. The right heart chambers are rarely involved The endocardium is diffusely thickened, smooth, and porcelain-white The valves are also affected at times. The subendocardial thickening is due to a marked proliferation of the collagen and elastic tissue which



[1] This work was done in collaboration with the late Dr. R. F. Dillon.

diastole Some observers have emphasized that the ratio of the end-diastolic to the systolic pressure in the right ventricle does not exceed 1:3, except in chronic constrictive pericarditis (Yu). However, exceptions occur. The left atrial and left ventricular pressure pulses also show an early-diastolic dip and plateau in constrictive pericarditis. A marked elevation of the pulmonary wedge pressure is usually present, indicating left ventricular involvement In fact, the mean right atrial and pulmonary wedge pressures in chronic constrictive pericarditis are usually approximately equal because the alteration in ventricular distensibility involves both ventricles to a similar degree. The pulmonary arterial pressure usually shows a small pulse pressure because there is a marked increase in the diastolic and very little rise in the systolic pressure (Burwell). In response to exercise, a further rise in the right atrial, right ventricular, pulmonary artery, and pulmonary wedge pressures is observed

HEMODYNAMICS OF SUBENDOCARDIAL FIBROELASTOSIS

This condition is rare. Although it may occur in adults, most of the cases occur in the pediatric age group The published data of right heart catheterization in patients with subendocardial fibroelastosis report normal or slightly increased pulmonary artery and pulmonary wedge pressures (Adams). Of 26 patients with subendocardial fibroelastosis studied by the authors, six, ranging in age from 6 months to 10 years, have been studied by right heart catheterization. In four of these patients, left heart catheterization was also performed The findings of left heart catheterization, to the best of the authors' knowledge, have not been reported previously by other authors. In four patients, the diagnosis was confirmed at autopsy The right heart cathe-

sures and a prominent, *early-diastolic dip* in the atrium and ventricle (Bloomfield) The early-diastolic dip is followed by a plateau These phenomena are best seen in the ventricular pressure-pulse tracings (Fig 16-29A). There are two well-marked negative waves (dips) in the right atrial pressure tracing during the cardiac cycle, one in early diastole, the other during ventricular systole (Fig. 16-29B).

In the normal heart, the volume changes associated with filling of the ventricles result in only slight pressure changes. When ventricular distensibility is impaired, marked changes in pressure occur. Hence the catheterization data show elevation of the right ventricular diastolic and the mean right atrial pressures. Because the maximal diastolic volume of the ventricle is fixed, ventricular filling is rapidly completed, and the pressure tracing shows a sharp rise after the early diastolic dip and a sustained high pressure, referred to as a *diastolic plateau*, during the remainder of

also compatible with myocardial impairment or failure may be encountered in fibroelastosis associated with slight left ventricular dilatation or in the contracted rather than the dilated type of fibroelastosis. In the latter, the physiologic findings appear to be simply those of left ventricular failure with an elevated left ventricular diastolic pressure and no characteristic changes in the pressure pulse contours. The right heart catheterization data usually demonstrate mild to moderate pulmonary hypertension. The pulmonary wedge pressures are usually elevated. These findings are secondary to the changes involving the left side of the heart. Further study of this subject is certainly indicated.

terization data showed *variable degrees of pulmonary hypertension,* which was mild to moderate in four. The pulmonary artery systolic pressures ranged from 34 to 56 mm Hg. In two patients, however, the pressures were more than 80 mm Hg. One of the latter patients showed at autopsy some degree of mitral stenosis besides fibroelastosis of the left ventricle; the other patient had no evidence of mitral stenosis at autopsy. The pulmonary wedge pressures were definitely elevated in four patients, normal in one, and not obtained in another. The calculated total pulmonary resistances were elevated in all patients and markedly increased in the two who had pulmonary pressures greater than 80 mm Hg. The pulmonary arteriolar resistances were also *markedly increased* The peripheral arterial oxygen saturation was normal, except in one patient in whom it was very slightly diminished. The calculated cardiac index was within the range of normal in three but diminished in the other three patients (Table 16-6).

Because of the presumption that subendocardial fibroelastosis behaves like constrictive pericarditis when it involves the left ventricle, it is of interest to determine whether the left ventricular pressure-pulse changes resemble those of constrictive pericarditis This problem may be solved by combined right and left heart catheterization Indeed, without left heart catheterization data, it is not possible to be sure whether pulmonary hypertension and elevation of the pulmonary wedge pressures reflect a mitral valve lesion, involvement of the left ventricle, or a combination of these lesions.

The mean left atrial pressures were markedly elevated in three patients, and slightly elevated in one (Table 16-7). In two of these patients, the left ventricular diastolic pressures corresponded with the left atrial pressures at similar times in the cardiac cycle. In one patient, besides an elevated left ventricular diastolic pressure, there was an increase in the "left atrial V" wave suggestive of slight mitral regurgitation,[2] these findings are consistent with the valvular changes seen in this condition. In one patient in whom it was not possible to enter the left ventricle, but only the left atrium, no evidence *of mitral stenosis was found* at autopsy. In all three patients, the left ventricular diastolic pressures were elevated to levels consistent with left ventricular failure The left ventricular pulse-pressure tracing revealed *no evidence* of an early-diastolic dip and plateau in two patients (Fig 16-30). In one patient, the tracing showed an early-diastolic dip followed by a sharp rise in pressure, the latter being due in part to atrial contraction which gives the impression of a short diastolic plateau (Fig 16-31) It is of interest to note that this patient (now 10 years old) has never been in heart failure, showed only slight to moderate cardiac enlargement on radiography, and had moderate pulmonary hypertension and a left ventricular end diastolic pressure of 29 mm Hg Four years previously, a negative surgical exploration for suspected mitral stenosis had been performed Excision of the left atrial appendage revealed marked thickening due to fibroelastosis. It is presumed that the same condition is present in the left ventricle The two patients whose left ventricular pressure tracings revealed no evidences of an early-diastolic dip and plateau had been in heart failure previously, showed evidence of cardiac enlargement, and their heart rates were faster than that in the previous patient.

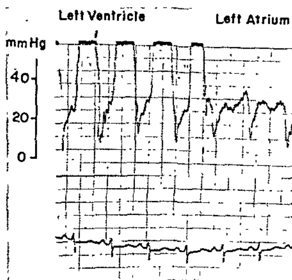

Fig. 16-31. Left ventricular and left atrial pressure pulse obtained by pull-back from left ventricle, illustrating early-diastolic dip followed by sharp rise in pressure.

CONCLUSIONS

These facts suggest that hemodynamic findings compatible with a constrictive lesion but

[2] The so-called left atrial V wave is actually a late-systolic wave of regurgitation For details, see Part 4, Chap 12 and Part 7, Chap. 14. *Editor.*

ble, at least in their superficial portions The more frequent multiverrucous type appears as a band of yellowish-tan *verrucae* or vegetations at the line of closure of a moderately thickened valve. Involvement of the commissures and corpora arantii of the aortic valve is not infrequent, but the mural endocardium and valve pockets are characteristically spared. Although all valves may be affected, the mitral and aortic, either singularly or together, represent the most frequent sites of degenerative verrucal endocardiosis.

Microscopically, affected valves reveal focal or diffuse swelling and degeneration of valvular collagen The latter assumes a pronounced eosinophilia in sections stained with hematoxylin and eosin Remnants of collagen may be identified in such areas by appropriate staining techniques In addition, degenerated foci are argyrophilic, markedly resistant to tryptic digestion, and may appear orange when stained by the phosphotungstic acid–hematoxylin method (Allen and Sirota, Fisher and Baird) The tinctorial features are similar to those of fibrinoid rather than fibrin or unaltered collagen. Protrusion of this material on to the surface of the valve may occur and constitute the entire vegetation. More frequently, fibrin thrombi appear superimposed upon such an altered endocardial surface (Fig. 16-33) Similar foci of altered valvular collagen may be observed within the valve without apparent herniation. There is a notable paucity of inflammatory cells within the valve, although small collections of neutrophils, lipid-laden macrophages, and an occasional *Anitschkow myocyte* may be observed, particularly in superficial areas Bacterial masses are not encountered and culture of the vegetations is negative It is conceivable, however, that this condition may be encountered since bacterial growth may occasionally be obtained from apparently normal valves (Epstein and Kugel). It has been suggested that the so-called *excrescences of Lambl* may represent healed forms of degenerative verrucal endocardiosis (Allen and Sirota).

The absence of significant inflammatory reaction or destruction of the valve in degenerative verrucal endocardiosis readily allows for its differentiation from acute and subacute bacterial endocarditis. The former feature, as well as lack of Aschoff bodies, help distinguish it from rheumatic valvulitis Although morphologically the lesions of atypical verrucous endocarditis may appear identical with those of degenerative verrucal endocardiosis, the location of the former and its association with other visceral manifestations of lupus erythematosus allow for their differentiation.

The clinical significance of degenerative verrucal endocardiosis has been reemphasized by

Fig. 16-33. Section of aortic valve with verruca comprised of fibrin and fibrinoid Small foci of fibrinoid degeneration are also apparent within valve substance (1). Inflammatory reaction is characteristically absent.

I

Degenerative verrucal endocardiosis

EDWIN R. FISHER

Degenerative verrucal endocardiosis (nonbacterial thrombotic endocarditis) is a form of valvular heart disease with macroscopic and morphologic features which are distinct from those of the bacterial, rheumatic, or syphilitic types. The term is synonymous with "nonbacterial thrombotic indeterminate endocarditis" as used by Libman and Gross and Friedberg. Other designations, such as "terminal" or "marantic" endocarditis or *endocarditis simplex* or *minima*, appear unsatisfactory since they imply that these lesions are of little clinical significance or represent a terminal event during the course of a fatal illness. Indeed, they may be directly responsible for death (Fisher and Baird; MacDonald and Robbins), or act as a nidus for bacterial endocarditis (Allen and Sirota). The term "degenerative verrucal endocardiosis" (Allen and Sirota) aptly indicates the morphogenesis and noninflammatory nature of the lesions.

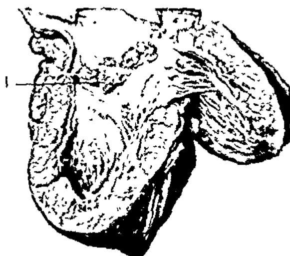

Fig. 16-32. Large multiverrucous form of degenerative verrucal endocardiosis of aortic valve (I) of heart from patient with mucinous carcinoma of lung

Although degenerative verrucal endocardiosis may be noted in a variety of diseases, approximately one-third of the recorded cases have been associated with *malignant neoplasms* and, in a similar number, *congestive cardiac failure* was apparent. It is of interest that arteriolar lesions with similar morphologic and tinctorial features may be observed in some patients with degenerative verrucal endocardiosis and carcinoma (Fisher and Baird) or thrombotic thrombocytopenic purpura (Friedberg and Gross; Singer et al.). The occurrence of this form of valvular disease in cases with inactive or chronic rheumatic heart disease has been emphasized (Gross and Friedberg). However, MacDonald and Robbins found the latter in only 18 per cent of 78 examples of degenerative verrucal endocardiosis. On the other hand, arteriosclerotic heart disease was encountered in more than one-half of their cases. In 10 per cent of the cases, evidence of antecedent heart disease was absent. There [illegible] ...lection for [illegible] have [illegible] ...ugh been observed at all decades of life, ... the majority have been noted after the age of fifty.

Grossly, the lesions may be variable. They may be solitary (univerrucous) or multiple (multiverrucous), and their size may range from several millimeters to one or more centimeters (Fig. 16-32). Small lesions are rather *firmly* adherent to the valves, whereas the larger, more globose types are somewhat fra-

14

Left atrial myxoma and ball-valve thrombus

WILLIAM LIKOFF

Primary tumors of the heart are uncommon. The most prevalent are *endocardial myxomas* which occur mainly within the atria. A controversy exists as to whether these structures are true neoplasms or *thrombi* which have undergone myxomatous degeneration. Because this uncertainty cannot be resolved, left atrial myxomas and ball-valve thrombi are considered as a generic topic in the present discussion.

Recent diagnostic refinements have reduced the difficulty of recognizing these lesions. Precise studies, such as angiocardiography, have made it possible to correlate their presence with the signs and symptoms which they initiate. Of equal importance, these actual or pseudotumors have been removed successfully under hypothermia or with the aid of the cardiopulmonary bypass. This promise of proper recognition and effective treatment accounts for the intense interest currently being expressed on a subject which heretofore had been considered singularly rare and unimportant.

PATHOLOGICAL CONSIDERATIONS

Approximately 80 per cent of intraatrial tumors occur on the left side. They arise in the region of the mural endocardium, where the preferred sites of origin include the area of the foramen ovale, the pulmonary veins, and the auricular appendage, or from the heart valves themselves, most notably the mitral.

In the early medical literature these lesions generally were considered neoplastic (Thorel). More critical evaluation of the illustrations cited indicated that they actually represented thrombi in various stages of organization (Husten). However, many authors continue to favor the interpretation that these atrial tumors are cellular in origin. Support for this position is derived from the following observations: (1) They are not found in the ventricles, where thrombus formation is so common. (2) They frequently occur without concomitant thrombus formation in the adjacent appendage. (3) There rarely is evidence of stratification, which would be expected in thrombi. (4) On microscopic examination, stellate cells, lymphocytes, and plasma cells, all characteristic of a neoplasm, are observed.

Theoretically, there should be additional proof that these structures arise in a definite location and have a uniform appearance. However, those reported in the literature varied considerably in size, contour, and consistency. They have been thick and irregular or villous and smooth, they have been firm or gelatinous; they have been attached to the endocardium by a long, narrow stalk or by a broad base.

The microscopic findings also have been inconsistent (Fig. 16-34). The amorphous material forming the ground substance of the tumor has stained like mucin or has not. A great variety of cells has been seen including the stellate type, typical of myxomatous tissue, inflammatory elements, such as lymphocytes and plasma cells, large multinucleated structures; and

MacDonald and Robbins. Emboli with infarction were noted in 14 per cent of their cases, and in many of these such events dominated the clinical picture. The tinctorial features of the emboli are frequently identical with those of the valvular lesion, containing both fibrinoid and fibrin (Fisher and Baird). The role of degenerative verrucal endocardiosis in the pathogenesis of some cases of bacterial endocarditis has been indicated by Allen and Sirota.

The pathogenesis of degenerative verrucal endocardiosis has not been elucidated The possibility that such lesions may represent a manifestation of hypersensitivity, although attractive and not implausible, requires more convincing proof Further studies are necessary.

recurrent the symptoms are evanescent, identical with those usually encountered in rheumatic mitral stenosis, and out of proportion to the degree of demonstrable heart disease The diagnosis of this type of tumor may be further suggested by a negative past history for rheumatic fever However, approximately one-half of the patients with unmistakable rheumatic endocarditis have no knowledge of previous activity.

When the myxoma or ball-valve thrombus causes a sudden complete obstruction to ventricular filling, a curious type of circulatory failure develops, accompanied by a shock-like syndrome.

Occasionally, the mitral valve or the pulmonary vein openings are partially blocked by a myxoma which maintains a fixed position within the left atrium (Likoff et al) The clinical manifestations of this type of lesion cannot be differentiated from ordinary rheumatic *mitral stenosis*

Transient Mitral Valve Obstruction. A number of cases have been collected and reported in which polypoid myxomas or thrombi of the left atrium have brought about an intermittent occlusion of the mitral orifice This transient obstruction to blood flow produces the hemodynamic and clinical abnormalities of mitral stenosis. However, it has been a common experience that *these symptoms and signs are markedly altered by changes in body position, which influence the relation of the myxoma to the mitral valve opening.*

With the recurrent obstruction, there is an exacerbation of the ordinary symptoms of functional mitral stenosis including dyspnea. *Extreme respiratory embarrassment including pulmonary edema is more likely to develop in response to a particular position rather than to exercise.* This also characterizes such complaints as precordial discomfort and the sensation of a rapid or irregular cardiac action Certain uncommon manifestations have been encountered, especially *cyanosis*, *vertigo*, and *syncope*. On occasion, *convulsions accompany* the loss of consciousness

Rapidly developing and persistent heart failure also has been attributed to intraatrial myxomas which temporarily block the mitral valve or pulmonary vein openings In some instances, the sudden, unexpected, and *unexplained* development of heart failure has been quite remarkable However, as long as the tumor maintains a *changing* position in relation to the critically important intracardiac orifice, congestive *failure is not* intractable. If improvement occurs during ordinary therapeutic meas-

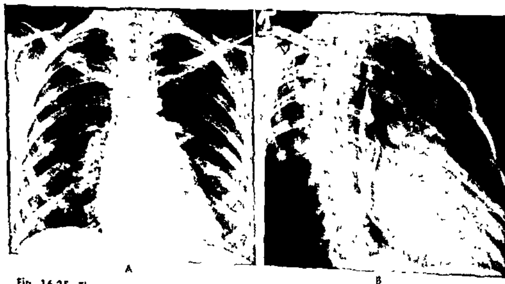

Fig 16-35. These roentgenographic pictures illustrate, (A) in the PA view, the fullness of the pulmonary segment giving rise to a "mitralized" left cardiac border, and (B) in the RAO, the posterior displacement of the barium-filled esophagus by the enlarged left atrium; seen in a patient with left atrial myxoma

Fig 16-34. The photomicrograph shows the structure of a myxoma removed from the left atrium. It clearly appears to be an edematous thrombus in the late stages of organization. The resemblance to edematous granulation tissue is striking.

erythrocytes Blood vessels have been observed, but even these vary very significantly in frequency and caliber. In many instances, they have appeared only as capillaries with endothelial walls through which the erythrocytes and the blood pigments hemosiderin and hematoidin have extravasated

Certain of these gross and microscopic findings have been listed as being most suggestive of a myxoma Thus, Gould, modifying the initial observations of Fabris, considers the diagnosis likely when the tumor arises in the area of the mitral valve or foramen ovale from a thin pedicled base, and when it is a thick, but transparent and soft, lesion with a continuous endocardial covering. On microscopic examination, stellate cells are distributed alone or in syncytial groups in a peculiar colorless stroma which stains like mucin.

In contrast, an organized thrombus is more likely to originate within the atrium as a regular, opaque, firm tumor with an endocardial covering only at the junction of implantation. The cells consist mainly of inflammatory elements and erythrocytes, which are stratified in several layers. Mucin is not present.

The ability to distinguish a myxoma from a thrombus frequently is compromised because certain features may be common to both lesions. For example, a myxoma may simulate a thrombus by containing a profusion of erythrocytes and hemosiderin microscopically, and by having fibrin on its free surface On the other hand, the center of a large organized thrombus may be replaced by fibrous tissue which can resemble diffusely distributed myxomatous material.

Acknowledging the complexity of the problem, Husten classified intraatrial tumors as either thrombi, myxomas, or structures which could not be accurately defined. Later, he questioned the existence of a true neoplasm and suggested that all of these lesions represented the end results of organized thrombi. This view deserves particular emphasis In all likelihood, it is reasonable and accurate. *All pedunculated structures arising from within the atria should be regarded as thrombi unless the evidence to the contrary is very compelling indeed* The major exceptions to this conservative view are the growths originating from the heart valves themselves, which are probably true tumors. These invariably are larger than most thrombi and are exceptionally well organized. The key sign that this or any other intracardiac myxoma represents an actual neoplasm which arises in rests of embryonic mucoid tissue is the demonstration of a localized proliferation of mucous tissue within the endocardium (Mahaim). However, the infrequency of this finding supports the concept that a myxoma is merely a thrombus which has undergone some degree of organization.

CLINICAL MANIFESTATIONS

Left atrial myxomas may be discovered during autopsies, even when previous histories and exacting physical, as well as laboratory, examinations have not suggested their presence It is not known how long these tumors do or can remain asymptomatic

On the other hand, myxomas can cause important clinical signs. These occur when they obstruct an orifice and impair the intracardiac flow of blood If the impediment to the flow of blood across the mitral valve is transient and

recurrent the symptoms are evanescent, identical with those usually encountered in rheumatic mitral stenosis, and out of proportion to the degree of demonstrable heart disease. The diagnosis of this type of tumor may be further suggested by a negative past history for rheumatic fever However, approximately one-half of the patients with unmistakable rheumatic endocarditis have no knowledge of previous activity.

Later, he questioned the existence of a true neoplasm and suggested that all of these lesions represented the end results of organized thrombi. This view deserves particular emphasis. In all likelihood, it is reasonable and accurate *All pedunculated structures arising from within the atria should be regarded as thrombi unless the evidence to the contrary is very compelling indeed* The major exceptions to this conservative view are the growths originating from the heart valves themselves, which are probably true tumors These invariably are larger than most thrombi and are exceptionally well organized The key sign that this or any other intracardiac myxoma represents an actual neoplasm which arises in rests of embryonic mucoid tissue is the demonstration of a localized proliferation of mucous tissue within the endocardium (Mahaim). However, the infrequency of this finding supports the concept that a myxoma is merely a thrombus which has undergone some degree of organization

CLINICAL MANIFESTATIONS

Left atrial myxomas may be discovered during autopsies, even when previous histories and exacting physical, as well as laboratory, examinations have not suggested their presence It is not known how long these tumors do or can remain asymptomatic.

On the other hand, myxomas can cause important clinical signs These occur when they obstruct an orifice and impair the intracardiac flow of blood If the impediment to the flow of blood across the mitral valve is transient and

recurrent the symptoms are evanescent, identical with those usually encountered in rheumatic mitral stenosis, and out of proportion to the degree of demonstrable heart disease The diagnosis of this type of tumor may be further suggested by a negative past history for rheumatic fever However, approximately one-half of the patients with unmistakable rheumatic endocarditis have no knowledge of previous activity

When the myxoma or ball-valve thrombus causes a sudden complete obstruction to ventricular filling, a curious type of circulatory failure develops, accompanied by a shock-like syndrome

Occasionally, the mitral valve or the pulmonary vein openings are partially blocked by a myxoma which maintains a fixed position within the left atrium (Likoff et al) The clinical manifestations of this type of lesion cannot be differentiated from ordinary rheumatic mitral stenosis.

Transient Mitral Valve Obstruction. A number of cases have been collected and reported in which polypoid myxomas or thrombi of the left atrium have brought about an *intermittent* occlusion of the mitral orifice This transient obstruction to blood flow produces the hemodynamic and clinical abnormalities of mitral stenosis. However, it has been a common experience that *these symptoms and signs are markedly altered by changes in body position, which influence the relation of the myxoma to the mitral valve opening*

With the recurrent obstruction, there is an exacerbation of the ordinary symptoms of functional mitral stenosis including dyspnea. *Extreme respiratory embarrassment including pulmonary edema is more likely to develop in response to a particular position rather than to exercise.* This also characterizes such complaints as precordial discomfort and the sensation of a rapid or irregular cardiac action. Certain uncommon manifestations have been encountered, especially *cyanosis, vertigo,* and *syncope.* On occasion, *convulsions* accompany the loss of consciousness.

Rapidly developing and persistent heart failure also has been attributed to intraatrial myxomas which temporarily block the mitral valve or pulmonary vein openings In some instances, the sudden, unexpected, and unexplained development of heart failure has been quite remarkable. However, as long as the tumor maintains a changing position in relation to the critically important intracardiac orifice, congestive failure is not *intractable* *If improvement occurs during ordinary therapeutic meas-*

Fig 16-35 These roentgenographic pictures illustrate, (A) in the PA view, the fullness of the pulmonary segment giving rise to a "mitralized" left cardiac border, and (B) in the RAO, the posterior displacement of the barium-filled esophagus by the enlarged left atrium; seen in a patient with left atrial myxoma

Fig. 16-34. The photomicrograph shows the structure of a myxoma removed from the left atrium. It clearly appears to be an edematous thrombus in the late stages of organization The resemblance to edematous granulation tissue is striking.

erythrocytes Blood vessels have been observed, but even these vary very significantly in frequency and *caliber* In many instances, they have appeared *only as capillaries* with endothelial walls through *which the* erythrocytes and the blood pigments hemosiderin and hematoidin have extravasated

Certain of these gross and microscopic findings *have* been listed as being most suggestive *of a myxoma* Thus, Gould, modifying the initial *observations* of Fabris, considers the diagnosis likely when the tumor arises in the area of the mitral valve or foramen ovale *from a thin* pedicled base, and *when it is* a thick, but transparent and *soft, lesion* with a continuous endocardial covering. On microscopic examination, stellate cells are distributed alone or in *syncytial* groups in a peculiar colorless stroma which stains like mucin

In contrast, an organized thrombus is more *likely* to originate within the atrium as a regular, opaque, firm tumor with an endocardial *covering only* at the junction of implantation. The cells *consist* mainly of inflammatory elements and erythrocytes, which are stratified in several layers. Mucin is not present.

The ability to distinguish a myxoma from a thrombus frequently is compromised because *certain* features may be common to both lesions. For example, a myxoma may simulate a thrombus by containing a profusion of erythrocytes and hemosiderin microscopically, and by having fibrin on its free surface. On the other hand, the center of a large organized thrombus may be replaced by fibrous tissue which can resemble diffusely distributed myxomatous material.

Acknowledging the complexity of the problem, Husten classified intraatrial tumors as either thrombi, myxomas, or structures which could not be accurately defined Later, he questioned the existence of a true neoplasm and suggested that all of these lesions represented the end results of organized thrombi This view deserves particular emphasis In all likelihood, it is reasonable and accurate *All pedunculated structures arising from within the atria should be regarded as thrombi unless the evidence to the contrary is very compelling indeed.* The major exceptions to this conservative view are the growths originating from the heart valves themselves, which are probably true tumors These invariably are larger than most thrombi and are exceptionally well organized The key sign that this or any other intracardiac myxoma represents an actual neoplasm which arises in rests of embryonic mucoid tissue is the demonstration of a localized proliferation of mucou tissue within the endocardium (Mahaim) However, the infrequency of this finding sup ports the concept that a myxoma is merely thrombus which has undergone some degre of organization.

CLINICAL MANIFESTATIONS

Left atrial myxomas may be discovered du ing autopsies, even when previous histories an exacting physical, as well as laboratory, exam inations have not suggested their presence I is not known how long these tumors do or ca remain asymptomatic

On the other hand, myxomas can cause im portant clinical signs. These occur when the obstruct an orifice and impair the intracardia flow of blood If the impediment to the flow o blood across the mitral valve is transient an

nique in these early efforts was predicated upon the principles of closed-heart surgery.

The first successful operation was reported by Crafoord, who utilized hypothermia and an open technique This triumph now has been followed by others (Scannell et al, 1956).

It is evident that consistent results in the removal of left intraatrial myxomas are much more likely when the atrial wall is incised and the surgery is performed under direct vision. Otherwise, the risk of systemic arterial embolization from fragmentation of the tumor would be considerable. The use of the heart-lung pump to bypass the function of the left heart affords the means of an effective and reasonably safe approach to the problem.

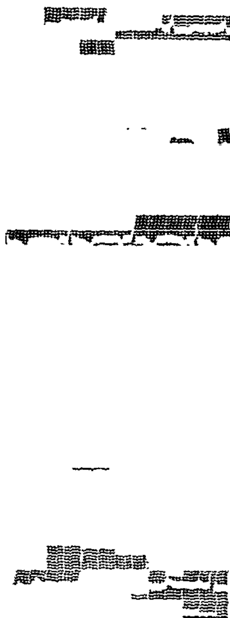

Fig. 16-36. The electrocardiogram shows bifid P waves in leads I and II and inversion of the T waves in leads II and III, seen in a patient with left atrial myxoma.

ures, the causative lesion still may remain obscure.

The *auscultatory findings* may be typical of mitral stenosis or may be bizarre and inconclusive. *In either instance,* the salient clinical point is the fact that the character, if not the actual presence of these events, may change with the position of the patient

The contour of the heart, as revealed by standard roentgenologic examination, may reveal straightening of the left border and prominence of the left pulmonary salient, accompanied by left atrial enlargement (Fig 16-35). These abnormalities, however, are modest when the obstruction to the mitral inlet is incomplete as well as transient. Very often this fact is the key to a proper diagnosis.

The *electrocardiogram* is not distinctive or helpful (Fig. 16-36). It may depict P-wave abnormalities or paroxysmal arrhythmias particularly atrial fibrillation or flutter. However, atrioventricular or intraventricular conduction defects and S-T segment or T-wave abnormalities, commonly reported in secondary tumors of the heart, are not usually encountered

Cardiac catheterization has indicated that, when an intraatrial myxoma causes a fixed degree of mitral valve obstruction, the pressures within the right ventricle, the main pulmonary artery, the left atrium, and the pulmonary capillary system become abnormally elevated (Mahaim). It is reasonable to suspect that a similar, but temporary, hemodynamic pattern is created when the obstruction is transient.

Angiocardiography is the most reliable method of making a definite diagnosis. The radiopaque material can be injected directly into the left atrium by utilizing the puncture technique employed in left heart catheterization. The myxoma then appears as a distinct filling defect (Fig. 16-35).

Sudden Complete Mitral Valve Obstruction. A large, pedunculated left atrial ball-valve myxoma or thrombus may completely occlude the opening of the mitral valve, critically impair left ventricular filling, and result in sudden death. This may occur without previous indications of an atrial tumor or it may succeed symptoms caused by a periodic impediment to ventricular filling.

Occasionally, when the complete obstruction develops gradually and inexorably, distinctive signs appear which suggest the diagnosis before the patient succumbs. The upper and lower extremities become cold and mottled *Localized areas of cyanosis and of actual necrosis appear at the tips of the fingers or toes.* Finally a state of profound shock develops and persists Death may not occur for several days, during which time consciousness may not be impaired

TREATMENT

Functional cardiovascular disturbances and the effects of stress

STEWART WOLF

All bodily disorders and diseases are functional and at the same time organic in the sense that they produce discomfort or disease in the patient by disturbing the function of one or more of the bodily organs, or organ systems Thus, congestive heart failure, irrespective of its etiologic basis, is a functional disturbance One of the major alterations in function is undue retention of salt and water All of the factors responsible for activating the pathogenic mechanisms are not understood They doubtless include weakness of the myocardium and ischemia of the kidney, but it is also apparent that, among other factors, impulses arising in the interpretive areas of the brain are capable of altering salt and water excretion They may thus enter the complex of congestive failure. Schottstaedt et al. have shown on one hand, a substantial diuresis of sodium and water and, on the other, a significant retention under differing stressful circumstances occurring in healthy subjects as well as those with impaired cardiac function Cathey et al have adduced evidence that stressful life situations may induce an elevation of serum cholesterol and lipoproteins of the S_f 12 to 20 range It is probable that most adaptive functions of the cardiovascular system are responsive to stimuli which owe their force to their special significance to the individual. Thus, like disorders of the gastrointestinal tract, cardiovascular disorders can probably be augmented or perhaps actually initiated by stressful life situations, as well as by antigens, microorganisms, or nutritional, climactic, and traumatic stresses

Much of the confusion concerning the role of life stress in disease derives from failure to distinguish between cause and mechanism. All *mechanisms* are perforce organic and at the same time functional since they involve the functions of units of the body's equipment *Causes*, on the other hand, are likely to derive from the outside, often from noxious stimuli in the environment The causes, which may be multiple, activate the pathogenic mechanisms and produce bodily disorders and disease. The ability of symbolic stresses to participate in the activation of disease mechanisms depends upon the fact that most bodily organs are connected with and responsive to impulses reaching them via autonomic and endocrine pathways from the highest integrative centers of the nervous system, the interpretive areas of the brain.

The behavior of the heart and its tributary vascular channels is largely subject to control by autonomic nerves, locally manufactured chemical vasomotor substances, and chemicals within the general circulation, as well as by mechanical stimuli Some of these alterations in vascular behavior result in changes of secretory function, as in the stomach, of excretory function, as in the kidney, and in changes of permeability of vessels They also may be manifest in the form of painful distention of vessels, as in migraine headache.

The blood vascular system is responsible for nourishing the cells of the body; its vessels

penetrate virtually every organ, provide intercommunications among certain organs, and serve to integrate their activities. Changes in structure and function of any of the bodily organs may be related fundamentally to changes in blood flow, in the contractile state, or in the permeability of vessels. Pressure changes in an organ related to adjustments in hemodynamics *may also be of importance, as in the glomeruli* or in the sinusoids of the liver or spleen. When, as in some diseases and bodily disorders, structural changes implicate the vessels, vasculitis and perivascular inflammation may occur or there may be degenerative changes in the vessels themselves.

Some forms of hydrocephalus, glaucoma, and dermatitis owe their mechanisms primarily to alterations in vascular function Blood vas*cular alterations are also of leading* importance in hepatic cirrhosis, pneumonia, and ulcerative colitis. In fact, inflammation itself is essentially a vasomotor adaptation The consequences of the vasomotor adjustments depend on the locality in which the changes occur. Thus, constriction of cranial arteries may induce neurological deficits of varying degree, and dilatation, headache. Vascular engorgement in the turbinates, on the other hand, *causes stuffy nose* and may trap pathogenic organisms in the nasal and paranasal spaces, leading to infection Elsewhere, the consequences of vasodilatation and vasoconstriction vary with the site In the skin, vasoconstriction conserves body heat In the efferent arteriole of the glomerulus, it increases the pressure of urine filtration. In the liver, pressure changes resulting from vasomotor effects are manifest in the arteriovenous shunts of hepatic c rrhosis *Even more widespread pressure changes in the* venous system occur as part of the syndrome of congestive failure, or in the arterial system as arterial hypertension

It is well established that changes in function of the heart or blood vessels accompany emotional reactions, such as anger or excitement In fact, wherever vasomotor adjustments have been studied, e g , in the eye, nose, skin, stomach, colon, and general circulation, it has been shown that they are subject to influence by meaningful life situations.

CARDIAC FUNCTION

Cardiac Output. The work of Wolf and Wolff (1946) and later of Hickman et al. established that variations in stroke volume and cardiac output correspond with changes in life situation and emotional state. Later Duncan et al. related them to some of the symptoms of neurocirculatory asthenia. The possible importance of such alterations in cardiac function to patients with already damaged hearts has not been assessed. It is noteworthy, however, *that the work of the heart may be increased* and its efficiency affected by circumstances which constitute figurative burdens.

Muscular effort is a familiar stimulus to cardiovascular function. On the basis of the predictability in degree and duration of changes evoked by measured amounts of exercise, various workers have devised tests of adequacy of cardiac function and of cardiac reserve.

Briefly, expected changes include temporary *tachycardia and increase in the heart's output* of blood with each beat (stroke volume), followed by return to resting levels at a rate depending upon the amount of exertion undertaken. In healthy subjects, changes in the pattern of the electrocardiogram do not ordinarily occur with exercise; when they do, they are thought to indicate a degree of cardiac insufficiency and a reduction of the reserve capacity of the heart.

Tests of exercise tolerance have been difficult to interpret because factors other than exercise are capable of inducing tachycardia, increase in stroke volume, and even T-wave changes in the electrocardiogram (Stevenson et al , 1949). Prominent among such factors are life situations which are either consciously or unconsciously threatening to the security of the individual (Fig. 17-1). Situations of pleasurable anticipation may also be associ*ated with tachycardia* and an increase in stroke volume It is as if bodily changes were occurring in preparation for exertion, e g , fighting, running away, or active participation in some pleasurable situation. When exercise is actually undertaken under such circumstances, the cardiovascular adaptation may be excessive or unduly prolonged during recovery, as if a much greater muscular effort had been anticipated

Cardiac Rhythm. It has been observed that arrhythmias, including paroxysmal atrial tachycardia, extrasystoles, atrial fibrillation, and even the more serious paroxysmal ventricular tachycardia (Fig 17-2), occur in association with troublesome events in the day-to-day ex-

periences of individuals who have no other detectable evidence of heart disease It would appear that this variety of disorders of cardiac rhythm may be precipitated by or possibly fundamentally related to threats arising out of the life situation It is certainly unnecessary to postulate underlying structural disease of the myocardium as a cause of arrhythmias even in the case of such *potentially* serious disorders as atrial fibrillation and ventricular tachycardia

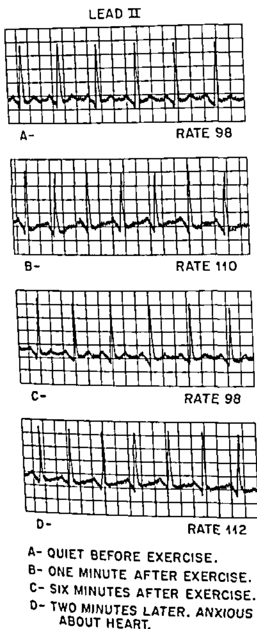

Fig 17-1. Marked depression of T waves in lead II of electrocardiogram. Essentially the same change was observed after exercise and during discussion of a stressful topic.

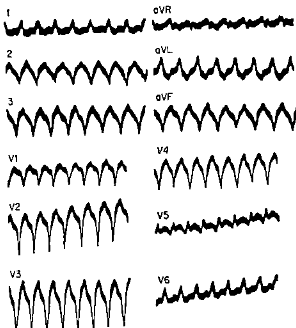

Fig. 17-2. Ventricular tachycardia occurring under stress in apparently healthy men without evidence of structural heart disease

The Electrocardiogram. Ordinarily when there are changes in the pattern of the electrocardiogram during exercise, the assumption is made that there is a disturbance of cardiac nutrition In the study of Stevenson et al., 19 patients displayed changes in S-T segments of T waves, to a degree considered significant according to the criteria of Master, following exercise performed during a period of stress. Six of the nineteen, or approximately one-third, failed to give any evidence of heart disease All had the symptoms previously described as characteristic of neurocirculatory asthenia and all but one were under 35 years of age The other 13 gave evidence of coronary arteriosclerosis In three patients, one with and two without other evidence of structural heart disease, exercise on a day of relative security and relaxation produced less change in the electrocardiogram than comparable exercise during anxiety.

In five of the six patients with neurocirculatory asthenia, and in all 13 of those with presumed coronary artery disease, it was possible to produce electrocardiographic changes during an interview covering pertinent personal problems, and without exercise or conscious anticipation of muscular effort The interesting

fact was that the changes induced during exercise were similar to those occurring during stressful interviews. In 14 of these instances, the heart rate immediately after exercise was nearly identical with that achieved during anxiety, and therefore the electrocardiographic complexes were fully comparable. In eight of these, the ECG during stress was identical with that following exercise. In four, the changes *during stress were greater than those induced* by exercise, and in two instances the changes were qualitatively different.

The changes observed in the ECG of one subject are shown in Fig 17-2 This patient, 32 years old at the time, had symptoms of palpitation and reduced exercise tolerance but gave no evidence of structural heart disease except for the ECG, which was normal at rest but in which T waves became inverted during exercise or during a stressful interview. Seven years later the patient still showed no further evidence of heart disease.

The mechanisms responsible for these changes cannot be stated on the basis of the data at hand. They may include coronary ischemia or perhaps merely sympathetic stimulation The interesting thing is that the changes with stress resulting from threats, symbols, or interpersonal relations are often similar to those following exercise

This information is in keeping with the general concept *that man during stress may react with his cardiovascular apparatus as if he were about to engage in strenuous muscular activity without any actual awareness of anticipating exercise.* Thus the electrocardiogram recorded during severe anxiety in a man with suspected coronary artery disease must be interpreted in the light of these findings Although the changes may be quickly reversible and may not always be of such grave import as is ordinarily thought, the possibility that repeated or sustained situational stress may lead to irreversible changes must be taken into consideration in planning therapy.

Congestive Heart Failure. As already pointed out, there is good evidence that mechanisms responsible for the retention of salt and water are connected with and responsive to impulses from the interpretive areas of the brain. Thus is provided a mechanism for either aggravation or mitigation of the manifestations of congestive heart failure in those patients with already impaired cardiac function. Experimental studies along this line have not been carried to the point of delineating to what extent such effects may be relevant to the bedside care of patients

PERIPHERAL VESSELS

Many important disturbances involving peripheral vessels are not customarily classified *among cardiovascular disorders These include* vascular headache, Raynaud's syndrome, hives, eczema, and various disorders of mucous membranes. The vasomotor mechanisms which appear to be responsible for these phenomena have been shown to be set in motion by a variety of stimuli, including situations or events which have a threatening significance to the individual.

Two familiar syndromes, migraine and Raynaud's disease, provide examples of vasomotor alterations in regional arteries which produce widely different symptoms. Both appear to be related chiefly to the attitudes and personality adjustment of the affected individual.

Ischemia and Tissue Damage. One way in which actual tissue damage may occur in response to changes in the function of peripheral blood vessels is through ischemia secondary to arterial constriction. It is well known in *Raynaud's syndrome,* for example, that damage to or loss of terminal phalanges may follow prolonged or persistently recurrent attacks.

In *migraine,* permanent ischemic damage to the brain has been shown to result from the preliminary vasoconstrictor phase when it has been exaggerated in degree or duration (Dunning et al.). *Cerebrovascular accidents* have been described in young individuals during periods of stress, and special proclivity for cerebral vascular contractility has been observed in such subjects using angiocardiographic techniques (Seidenberg et al.).

Tissue Damage Associated with Engorgement and Hyperemia. During the vasodilator phase of *migraine,* tissue damage may also occur. Subcutaneous extravasation of blood has been observed in an area where no mechanical trauma had been applied but where there had been extreme vasodilatation of a branch of the superficial temporal artery during an unusually intense migraine headache (Wolff et al).

The hazards of sustained engorgement of tissue, especially mucous membranes, include

a lowering of pain threshold and an increase in tissue fragility. In experiments on the stomach of a fistulous subject, it was repeatedly observed that noxious stimuli which did not induce pain when applied to the mucosa in its usual state did so when the membrane was in a state of sustained hyperemia and engorgement (Wolf et al). Likewise, relatively minor traumas, such as striking the membrane with a blunt glass rod or drawing a square of gauze over it, failed to produce a visible lesion when the membrane was in its usual state, but such maneuvers produced small hemorrhagic spots and erosions when they were applied to the *chronically* engorged mucosa. Often, in fact, small eroded areas appeared, apparently spontaneously, during a bout of unusually vigorous motor activity when the gastric mucosa was especially engorged

Thrombophlebitis and Phlebothrombosis. The work of Schneider et al has indicated a connection between certain types of emotional stress and intravascular clotting. He found in vitro an increase in blood viscosity with shortening of clotting time during circumstances productive of anxiety and resentment. In a group of patients with thrombophlebitis he was able to correlate clinical exacerbations with both the in vitro tests and the occurrence of conflict situations.

Atherosclerosis. There is renewed interest in the metabolism of cholesterol because of the possibility that atherosclerosis may be a nutritional disturbance of either intrinsic or extrinsic nature. Other factors which have been thought to be implicated are infection, climate, and glandular imbalance There is also growing interest in the relationship of vascular degeneration to stressful circumstances in our lives "Wear and tear" have for years been thought to underlie the pathogenesis of atherosclerosis and the disease states which are attributable to it, but the nature of the "wear and tear" has never been clearly defined So far, only fragmentary data are available to relate life stress to lipoprotein metabolism but, as mentioned above, recent studies indicate that certain situations of stress may be associated with a substantial rise in the level of blood cholesterol and an increase in lipoproteins of the S_f 12 to 20 category The relevance of such changes to the atheromatous process has, of course, not been established In this connection, the experimental findings of Cathey et al. have been reinforced by the observations of Groover, who found major rises in blood cholesterol in Air Force executives under stress. His data suggest that stress may be more important than diet in regulating cholesterol levels. However, these findings require confirmation.

Systemic Hypertension. It is an old observation, and very easily confirmed, that patients with essential hypertension, and normal subjects as well, display an increase in arterial pressure when brought into certain situations involving threats to their personal security. The pertinence of these responses to the initial causation or ultimate perpetuation of sustained arterial hypertension, however, *is not established* The investigator who studies hypertension is handicapped by the lack of relationship between level of the blood pressure and the presence or absence of symptoms, as well as the lack of uniformity and predictability of the natural course.

It has been shown, however, with appropriate documentation, that hemodynamic changes producing elevated arterial pressure, reduced renal blood flow, and increased blood viscosity occur as a part of an individual's adaptation to problems and challenges in his daily life (Wolf et al) Special attention has been directed to two contrasting patterns of hemodynamic adjustment which occur alike in hypertensive and normotensive individuals under stress One pattern appears to be identical with the "exercise" pattern, which is characterized by an increase in blood pressure explained by a rise in stroke volume without elevation of peripheral vascular resistance. The other pattern resembles that encountered in injury or hemorrhage. It is characterized by an increase in blood pressure attributable to an elevation in peripheral vascular resistance without a rise in stroke volume. When observed during interviews [illegible]
flicts,
manife[illegible]
tively [illegible], while the latter ("high resistance" pattern) was more often encountered with a calm exterior and evidence of suppression or repression of emotion.

In essential hypertension, there occurs a sustained increase in peripheral resistance without a rise in stroke volume There is, however, no significant difference between hypertensives

fact was that the changes induced during exercise were similar to those occurring during stressful interviews. In 14 of these instances, the heart rate immediately after exercise was nearly identical with that achieved during anxiety, and therefore the electrocardiographic complexes were fully comparable. In eight of these, the ECG during stress was identical with that following exercise. In four, the changes during stress were greater than those induced by exercise, and in two instances the changes were qualitatively different.

The changes observed in the ECG of one subject are shown in Fig. 17-2 This patient, 32 years old at the time, had symptoms of palpitation and reduced exercise tolerance but gave no evidence of structural heart disease except for the ECG, which was normal at rest but in which T waves became inverted during exercise or during a stressful interview. Seven years later the patient still showed no further evidence of heart disease

The mechanisms responsible for these changes cannot be stated on the basis of the data at hand. They may include coronary ischemia or perhaps merely sympathetic stimulation The interesting thing is that the changes with stress resulting from threats, symbols, or interpersonal relations are often similar to those following exercise

This information is in keeping with the general concept *that man during stress may react with his cardiovascular apparatus as if he were about to engage in strenuous muscular activity without any actual awareness of anticipating exercise.* Thus the electrocardiogram recorded during severe anxiety in a man with suspected coronary artery disease must be interpreted in the light of these findings Although the changes may be quickly reversible and may not always be of such grave import as is ordinarily thought, the possibility that repeated or sustained situational stress may lead to irreversible changes must be taken into consideration in planning therapy

Congestive Heart Failure. As already pointed out, there is good evidence that mechanisms responsible for the retention of salt and water are connected with and responsive to impulses *from the interpretive* areas of the brain. Thus is provided a mechanism for either aggravation or mitigation of the manifestations of congestive heart failure in those patients with already impaired cardiac function. Experimental studies along this line have not been carried to the point of delineating to what extent such effects may be relevant to the bedside care of patients.

PERIPHERAL VESSELS

Many important disturbances involving peripheral vessels are not customarily classified among cardiovascular disorders. These include vascular headache, Raynaud's syndrome, hives, eczema, and various disorders of mucous membranes. Subcutaneous extravasation of blood has been observed in an area where no mechanical trauma had been applied but where there had been extreme vasodilatation of a branch of the *superficial temporal* artery during an unusually intense migraine headache (Wolff et al).

The hazards of sustained engorgement of tissue, especially mucous membranes, include

2

Neurocirculatory asthenia

ARTHUR A. MILLER

This is a disorder characterized by many and varied symptoms (and few signs) referable to the cardiovascular system. It is not usually accompanied by structural damage to the heart, although at times this clinical syndrome may be superimposed upon organic cardiac disease. The most prominent symptoms include dyspnea, palpitation, left thoracic pain, nervousness, fatigue, dyspepsia, spells of dizziness, and "anxiety attacks." Friedberg states that what he designates as "neurocirculatory asthenia" or "cardiac neurosis" refers to "an ill-defined syndrome of psychogenic or neurogenic origin often mistaken for organic heart disease and characterized by dyspnea, precordial pain, palpitation, exhaustion, and a general incapacity or inefficiency in adjusting to physical or emotional strain." According to Walker, it occurs in 10 to 50 per cent of patients who visit cardiologists. It is thus a clinical syndrome of sufficient frequency and importance in clinical practice to deserve careful consideration of the mechanisms involved (somatic and psychological) in order to clarify diagnostic and therapeutic approaches.

Classical descriptions of this syndrome date from the American Civil War. During subsequent decades, particular attention has been given to this disorder in military situations. An increasing awareness of this problem in civilian life has, however, developed. Hartshorne (1864) described cases of "muscular exhaustion of the heart." DaCosta (1871) described the *irritable heart* and indicated recognition of the manifestations being due to a functional cardiac disorder. During World War I, a so-called "disordered action of the heart" or *soldier's heart* was described. Lewis (1917) designated the condition as *effort syndrome*. During World War I, a team of American Medical Reserve officers studied this condition in England and called it *neurocirculatory asthenia* (NCA) (Oppenheimer et al.). During and subsequent to World War II, there have been a number of papers on this disorder. Subsequent studies reflect efforts at more detailed clarification of the clinical manifestations and, quite significantly, attempts to integrate psychiatric observations.

From the foregoing and from the title of this section, it is apparent that the terminology applied to this disorder is not precise. There is no one designation which is consistently used and in the literature they seem to be used interchangeably. Cohen lists a number of terms, used in medical and neuropsychiatric literature and practice, to refer to a disorder with the above-described symptoms. These terms include neurasthenia, anxiety neurosis, neurocirculatory asthenia (NCA), nervous exhaustion, DaCosta's syndrome, effort syndrome, irritable heart, soldier's heart, somatization psychogenic cardiovascular reaction, somatization psychogenic asthenic reaction, anxiety reaction, vasomotor neurosis, névrose d'angoisse, personalities with mixed psychic and physical anomalies, and constitutional liability with tendency to functional disorders of specific organ systems. He states that, "the various terms used probably reflect more the special interests and theories of the various observers rather than a diversity of clinical disorders." This would certainly seem to be the case. With increasing understanding of the

and normotensives in their reaction to short-term stressful situations. Neither is there any correlation between an individual's response to interview and his reaction during a cold-pressor test, or between the type of vascular reaction to stress and the degree of vascular damage revealed by the eye grounds, heart size, or kidney function.

Further experimental studies have shown that the renal vasculature shares in the circulatory response to stressful events in the life situation. A decrease in effective renal plasma flow and an increase in filtration fraction occur in both hypertensive and normotensive subjects during a discussion of pertinent personal conflicts.

It is particularly notable that the mechanisms of the vascular apparatus responsible for raising the blood pressure in response to symbolic stimuli are not impaired by thoracolumbar or even "total" sympathectomy. Either the "exercise" or "high resistance" pattern may still occur, although there is no longer evidence of associated reduction in renal blood flow. It is conceivable that the loss of renal vasoconstrictor activity may protect the kidneys and thereby have a salutary effect on the course of essential hypertension. Perhaps it may be a factor in the apparent increased survival of sympathectomized patients even when there is no notable reduction of arterial pressure.

The significance of all these findings is not clear but there is nothing incompatible with the view that the *life adjustments in individuals with essential hypertension initially involve renal ischemia which may in turn set off a variety of endocrine and other humoral mechanisms with the ultimate development of irreversible tissue damage.* In any case, it is clear that stressful life experiences are sufficiently prominent, among stimuli which may elevate arterial pressure, to warrant their serious consideration in the clinical management of patients with essential hypertension. The evidence of emotional restraint and the calm exterior often displayed by these patients make it necessary for the physician to exercise special diligence and skill in uncovering meaningful life experiences and the attitudes and reactions associated with them.

A study of personality adjustment among the patients with hypertension does not delineate any characteristic personality "type," but yields strikingly similar data in regard to values, attitudes, and way of life. By and large, the hypertensives had grown up feeling the need to excel but at the same time to avoid conflict or too vigorous self-assertion. These strivings, often opposed, lead frequently to dilemmas and are manifested by wary, tentative, and noncommittal attitudes with respect to important interpersonal relations and major endeavors in life.

The results of therapeutic studies in essential hypertension will, of course, continue to be difficult to evaluate until methods are worked out to permit appraising the seriousness of essential hypertension and predicting its course. With all these limitations in mind, there is evidence enough to warrant the clinician's taking a serious interest in the background, life experience, and attitudes of his patient in the hope of helping him to a more constructive adjustment.

SUMMARY

A wide variety of vasomotor and hemodynamic disturbances in man have been examined from the standpoint of their relation to adverse or threatening life experiences. It would appear that cardiovascular functions in general are highly responsive to meaningful events and that a host of arrhythmias and peripheral vascular disorders may arise largely therefrom. The various hemodynamic mechanisms have been shown to respond to situations of which the force derives from their meaning to the individual; they respond to tangible stimuli in much the same way.

2

Neurocirculatory asthenia

ARTHUR A. MILLER

This is a disorder characterized by many and varied symptoms (and few signs) referable to the cardiovascular system It is not usually accompanied by structural damage to the heart, although at times this clinical syndrome may be superimposed upon organic cardiac disease The most prominent symptoms include dyspnea, palpitation, left thoracic pain, nervousness, fatigue, dyspepsia, spells of dizziness, and "anxiety attacks." Friedberg states that what he designates as "neurocirculatory asthenia" or "cardiac neurosis" refers to "an ill-defined syndrome of psychogenic or neurogenic origin often mistaken for organic heart disease and characterized by dyspnea, precordial pain, palpitation, exhaustion, and a general incapacity or inefficiency in adjusting to physical or emotional strain." According to Walker, it occurs in 10 to 50 per cent of patients who visit cardiologists. It is thus a clinical syndrome of sufficient frequency and importance in clinical practice to deserve careful consideration of the mechanisms involved (somatic and psychological) in order to clarify diagnostic and therapeutic approaches

Classical descriptions of this syndrome date from the American Civil War. During subsequent decades, particular attention has been given to this disorder in military situations An increasing awareness of this problem in civilian life has, however, developed Hartshorne (1861) described cases of "muscular exhaustion of the heart" DaCosta (1871) described the *irritable heart* and indicated recognition of the manifestations being due to a functional cardiac disorder During World War I, a so-called "disordered action of the heart" or *soldier's heart* was described. Lewis (1917) designated the condition as *effort syndrome* During World War I, a team of American Medical Reserve officers studied this condition in England and called it *neurocirculatory asthenia* (NCA) (Oppenheimer et al). During and subsequent to World War II, there have been a number of papers on this disorder Subsequent studies reflect efforts at more detailed clarification of the clinical manifestations and, quite significantly, attempts to integrate psychiatric observations

From the foregoing and from the title of this section, it is apparent that the terminology applied to this disorder is not precise There is no one designation which is consistently used and in the literature they seem to be used interchangeably. Cohen lists a number of terms, used in medical and neuropsychiatric literature and practice, to refer to a disorder with the above-described symptoms These terms include neurasthenia, anxiety neurosis, neurocirculatory asthenia (NCA), nervous exhaustion, DaCosta's syndrome, effort syndrome, irritable heart, soldier's heart, somatization psychogenic cardiovascular reaction, somatization psychogenic asthenic reaction, anxiety reaction, vasomotor neurosis, névrose d'angoisse, personalities with mixed psychic and physical anomalies, and constitutional lability with tendency to functional disorders of specific organ systems He states that, "the various terms used probably reflect more the special interests and theories of the various observers rather than a diversity of clinical disorders" This would certainly seem to be the case With increasing understanding of the

psychiatric aspects of this disorder, there have appeared terms consistent with this point of view, i.e., anxiety neurosis, anxiety state, cardiac neurosis, somatization psychogenic cardiovascular reaction, somatization psychogenic asthenic reaction. Some authors use the term neurocirculatory asthenia when "constitutional" factors seem to predominate and anxiety neurosis when psychological factors seem to predominate (Miles and Cobb, Oppenheimer). Oppenheimer, who coined the term *neurocirculatory asthenia* but sees the disorder as being a variant of anxiety neurosis, recommends retention of the above term since it is noncommittal and carries no connotation which will harm the patient so afflicted. Weiss (1939), on the other hand, feels that the term neurocirculatory asthenia does more harm than good, that it calls attention to a part of the disorder, that it implies that the circulation is at fault, that it confuses the patient, and often leaves the physician to feel that he understands the disorder because he has given it an imposing name. He recommends that "since neurocirculatory asthenia does not exist without neurosis or character disturbance, I suggest that we call it that, using the proper psychiatric designation, and adding qualifying terms if necessary." It is apparent that there is no term which adequately designates the total nature of this disorder. Weiss' point of view seems particularly pertinent if we remember that psychiatric designations do not exclude awareness of the contribution of "constitutional" or somatic factors in the origin of "psychiatric" disorders

Thus far in this chapter, it has been indicated that emotional factors must be seriously considered to gain any real understanding of this disorder. Throughout the pertinent literature, including the early description by DaCosta, there has been greater or lesser awareness that emotional factors play an important role. Concomitant with the development of psychodynamic understanding of anxiety, including its psychological and somatic manifestations, its psychological significance, and the psychological defenses brought to bear against it, there has been a commensurate evolution of understanding of the role of emotional factors in this disorder Despite the advance of understanding in this direction, there have been differing points of view as to the relative importance of the role played by the emotions. The author will, subsequently, consider psychological understanding relative to this disorder, but let us indicate, briefly, some representative points of view on this matter. Friedberg says that this disorder is not a nosologic entity, that "it is nothing more than a moiety of the more generalized picture of psychoneurosis, which, in the cases under discussion, chances to assume entirely or predominantly the garb of cardiac or circulatory symptoms. Hence, the term 'cardiac neurosis.'" Cohen et al, who have published several authoritative papers on this disorder, are considerably more reserved when it comes to the consideration of emotional factors. Their clinical descriptions appear to be essentially those of psychoneurosis. They use the term neurocirculatory asthenia as being synonymous with anxiety neurosis, neurasthenia, and effort syndrome. They say that they are "unable to distinguish between patients with neurocirculatory asthenia as diagnosed by cardiologists and those with anxiety neurosis and neurasthenia as diagnosed by psychiatrists." They, however, state that "a crucial causal relationship of this disorder to life situations and emotion-provoking situations has neither been proven nor disproven." They exclude a psychodynamic approach as being unscientific and believe that no techniques have been developed as yet to permit conclusive observations concerning the exact relationships, if any, of life situations and emotion-provoking situations to this disorder. Miles and Cobb believe that "unless one makes some attempt, not only to measure the constitutional or physiologic factors, but also to understand the psychodynamics of the illness and of the therapeutic processes as well, it seems unlikely that even the most objective and scientific investigations can prove fruitful." Oppenheimer sees the disorder as a variant of anxiety neurosis. Walker believes that physicians are dealing, not with heart disease, but with persons who complain of their hearts Others (Wittkower et al; Wood) consider emotional factors of major importance for the understanding of this syndrome

CLINICAL MANIFESTATIONS

This syndrome is said to occur more in women during peacetime while, during wars, there is a higher incidence in men There appears to be a rather high *familial incidence,*

and it has been stated that tall, slender individuals, and those engaged in occupations requiring prolonged concentration and anxious tension or physical strain, especially if there is an element of danger, are more prone to develop this syndrome than others It has been said that *infections, physical exhaustion, nervous prostration,* or *anxiety* can be accompanied or followed by NCA symptoms out of proportion to the original cause. The emotional significance of these experiences is probably more important in producing the syndrome than is the direct effect of these conditions The age incidence seems to be mainly between 20 and 40 years but it occurs at any time of life

Symptoms. DYSPNEA. This is the commonest and most distressing symptom It is characterized *mainly* by an inability to take a breath or a satisfactory breath. *Irregular, deep, sighing respiration* can be seen, for instance, on a BMR curve. Even at bed rest, there may occur an inability to take a deep breath, and there is not the panting such as follows exertion The incidence and degree of dyspnea is disproportionate to the degree of exercise and objective disturbance of ventilation. A so-called *hyperventilation syndrome,* i e., an outburst of dyspnea and tachycardia has been described There may be a psychogenic expression of a *fear of suffocation* and there may be *claustrophobia* Accompanying the respiratory difficulty may be *tachycardia, sweating,* a feeling of *anxiety, giddiness,* and, at times, *tetany* may result.

PRECORDIAL PAIN The pain may be either sharp, dart-like, intermittent, piercing, transient, and localized about the left nipple, or continuous, dull, and poorly localized in the left anterior hemithorax or substernal region. It is unrelated to effort, but sometimes occurs after tiring exertion Characteristically, unlike the pain of coronary heart disease, it does not compel the patient to stop activity nor does it seem to be relieved by rest There may be local tenderness in the precordium. A physiological mechanism for this pain and tenderness has been described (Wood, Friedman, 1948), apparently related to the effect of thoracic rather than diaphragmatic breathing

PALPITATION There is an awareness of the heart beat in the absence of arrhythmia, although often there may be tachycardia and forceful cardiac pulsations. The cardiac discomfort, pain, and intense anxiety may at times be accounted for by occasional premature beats or paroxysmal tachycardia.

FATIGUE. This can be chronic or occur in attacks It may consist of a sense of fatigue *upon arising in the morning* which diminishes during the day (it is to be noted that this symptom is not uncommon in psychological depressive reactions); or else, it may be a profound sense of exhaustion *following moderate physical exertion.*

PSYCHIC SYMPTOMS These are common and characteristic, and along with anxiety include phobic reactions, depressive reactions, and hypochondriacal symptoms A variety of other symptoms are observed and described. They include dizziness, sweating, cold clammy palms, nervousness, tremor, *headache,* flushing, frequent micturition, *insomnia,* paresthesia, faintness, diarrhea, difficulty in concentration, indecision, impairment of memory, and a tendency to mental, emotional, and physical *apathy.* Almost any bodily system may be involved in the symptomatology along with the cardiorespiratory system *In general, the symptoms appear related to "peripheral sympathetic manifestations" or "autonomic imbalance" and consequently any of the multitude of symptoms characteristic of this physiological state may appear.*

Objective Signs. Whereas the symptoms are multiple and varied, objective signs are not an especially prominent part of this clinical picture. As regards this condition per se, there are no objective signs of organic heart disease, but the disorder may occur with any form of structural cardiac pathology At times, the discovery that one has an organic heart disease may be followed by an increase in symptomatology, of the nature of NCA, which is not accounted for by the organic pathology. There may be *tachycardia,* which is related not to effort but to emotional attitudes There may be a mild fever, which is rarely over 100 5°. It has been observed that blood lactate is higher in NCA during moderate exercise than in control subjects Exercise may cause a rise in pulse rate greater than that in healthy subjects and with an abnormal delay of return At times, arrhythmias may be observed Basal metabolic rate, radiography, and ECG are normal, except for changes due to hyperventilation.

(Luisada, Friedberg, Cohen et al ; Walker.)

THE ROLE OF PSYCHOLOGICAL FACTORS

Anxiety. Advances in understanding of the psychobiological phenomenon of anxiety have provided a frame of reference for understanding such psychophysiological disturbances as the disorder now under consideration (Grinker and Robbins). In 1894, Freud described the symptomatology of *anxiety neurosis.* This clinical state included "general irritability, anxious expectation, anxiety attacks proper, rudimentary anxiety attacks (e.g., disturbances of heart action, disorders of respiration, sweating, tremors, ravenous hunger, vertigo, vasomotor neurasthenia, paresthesias), pavor nocturnus of adults, certain phobias" This phenomenological description of anxiety still holds true today. At that time, Freud considered that this phenomenon resulted from a transmutation of energy, i.e., if there were no capacity for outward expression of impulses (the blocked energy of sexual impulses, for instance), it became converted into anxiety. In subsequent developments of his theory of anxiety, Freud saw anxiety, not as a transmutation of energy of sexual impulses, but as a warning signal to the organism of some kind of danger

In the face of a situation of danger, one experiences a state characterized by psychological and physiological features, a sense of dread and foreboding, and the many physiological responses related to reactions of the vegetative nervous system Cannon described these physiological responses as preparing the organism for action in either fight or flight at a time of danger This, of course, is a necessary, healthy, warning and alerting response When, however, the response is greater than the external danger seems to require and when the response occurs without the presence of an apparent external danger, there exists an anxiety reaction with pathological implications Frequently, such anxiety occurs in the face of an individual's internal psychological conflict over impulses and thoughts which are psychologically unacceptable to him. When an apparent external danger is present, the response is usually designated as *fear;* when the response is disproportionate to the external danger or occurs without the presence of an obvious external danger it is designated as *anxiety* The actual psychophysiological responses of fear and anxiety are difficult to differentiate.

Individuals vary in the way in which they experience anxiety. Anxiety may be represented by parts of the total psychophysiological phenomenon. "Anxiety in the adult activates certain visceral patterns which are specific to the individual, no matter what the stress. Each one has his particular way of feeling anxious. Some variations include sinking abdominal sensations, diarrhea, vomiting, dyspnea, sensation of a lump in the throat, etc. Out of the generalized infantile precursors of anxiety, each person seems to have been conditioned to certain fragmentary visceral patterns which for him become accurate and faithful harbingers of intra-psychic danger" (Grinker and Robbins). In the light of this, it can be seen where cardiorespiratory symptoms can be representative of anxiety in a particular individual. Either these symptoms, cardiac and respiratory, may be the only representatives of anxiety or they may be the only evident ones, depending on the particular inclinations of the observer.

Anxiety is recognized as being common to all the neuroses The particular neurotic reaction, in fact, is considered to be the resultant of the types of psychological defense used to ward off the experiences of anxiety An individual may experience episodes of anxiety as such and thus be suffering from an anxiety neurosis Development of defenses against such an experience, varying with the types of defense, may result in such neurotic reactions as phobias, hysterical conversions, obsessive-compulsive neurosis, depression, and hypochondriacal reactions. In any of these conditions, there may be an array of symptoms which would meet the criteria of "neurocirculatory asthenia."

Psychogenic Factors and Constitutional Factors. Miles and Cobb emphasize multiple causative factors in disease, i.e., any particular disease state may be the result of the interplay of factors which they call (1) genogenic-hereditary, (2) chemogenic, (3) histogenic-structural, and (4) psychogenic. In the case of neurocirculatory asthenia, they consider a continuum, at one end of which are those cases primarily due to, for instance, genogenic and chemogenic factors· those patients who have evidence of a constitutional physiological deficit; and, at the other end of the continuum, those instances wherein psychogenesis is primary. Most patients fall between the extremes

of this continuum. Ross studied a group of neurocirculatory asthenia patients with the *Rorschach test*. He found that these patients presented features similar to those of psychoneurotics of other types. The NCA patients showed a tendency to give up in the face of difficulties as well as an obsessional conscientiousness which made their life problems appear more difficult to them than was necessary. He recognized cases of two general types (1) of long-standing nature and (2) of recent onset, and considered that the first type was possibly due to constitutional factors whereas the latter might be due more to current psychological stress. Jones and Scarisbrick delineated three groups of neurocirculatory asthenia patients.

1. Patients with poor physical endowment as the primary factor, these show effort intolerance since earliest recollection.

2. Patients similar to those in group 1 but differing in that they respond in a neurotic manner to their constitutional inferiority. In this group, there is a psychological origin but constitutional factors are basic. Emotional reactions that occur may assume any form, and the actual disability may be less than the person feels it to be.

3. Patients whose difficulties are primarily neurotic in nature. The clinical picture may be colored by constitutional factors but the latter are of secondary importance, or the clinical picture in this group may be wholly psychogenically determined.

There are a number of references in the recent literature wherein the role of psychological factors in this disorder is considered and documented (Oppenheimer, Walker, Weiss, Wittkower, Maloney, Kerr, Wood). Wittkower, studying a group of unselected soldiers with "effort syndrome," found none to be emotionally well adjusted and delineated five personality types among them. Wood emphasized that this syndrome is not a disease in itself and that it is a symptom complex usually occurring together with some psychiatric disease.

PHYSIOLOGICAL CONSIDERATIONS

Neurocirculatory-asthenic patients show responses which are quantitatively, not qualitatively, different from healthy subjects when exposed to various types of stimuli and stress (Cohen and White). The hyperthermia, giddiness, cardiovascular manifestations, respiratory manifestations, and "episodic neurogenic discharge," are said to be due to *hyperirritability of the sympathetic nervous system*, probably related to involvement of the hypothalamus (Friedman). There appear to be quantitative physiological differences between those patients with effort intolerance of lifelong duration and those patients who develop the disorder acutely under current stress (Jones and Scarisbrick). Patients with anxiety show a greater cardiovascular response to exercise than patients without anxiety (Stevenson et al.).

DIAGNOSIS

Diagnosis of this disorder depends, as does all diagnosis, on careful history taking and examination, followed by interpretation of the findings in the light of an understanding of the disease process and mechanisms. In this instance, particularly, an understanding of psychological phenomena and mechanisms—anxiety as a psychobiological phenomenon and defenses against anxiety—is particularly important for correct understanding, diagnosis, and treatment of this disorder.

Emotional disorders have their own distinct features that can be discovered by personality study and awareness of their manifestations. One can agree with Walker when he says that no greater blame should be attached to the physician who fails to make a physical examination than to one who fails to explore the mind. This point of view is particularly important in the type of disorder under consideration. It has been noted that the patient's choice of his presenting symptoms, psychological or physical, may determine whether the patient is referred to a psychiatrist or an internist. Depending upon the "prejudices" of the observer, the same disorder may be recognized as two different entities. The same patient may be diagnosed on successive hospitalizations as a victim of neurocirculatory asthenia, gastric neurosis, or anxiety neurosis, depending on the shift of emphasis on presenting complaints, all of which symptoms may be part of the total picture which are emphasized at various times. Exclusion of the existence of organic heart disease is an important diagnostic point. It is to be emphasized, however, that *neurocirculatory asthenia may exist when organic heart disease is also present,* in which instance there is no clear relationship between

THE ROLE OF PSYCHOLOGICAL FACTORS

Anxiety. Advances in understanding of the psychobiological phenomenon of anxiety have provided a frame of reference for understanding such psychophysiological disturbances as the disorder now under consideration (Grinker and Robbins). In 1894, Freud described the symptomatology of *anxiety neurosis.* This clinical state included "general irritability, anxious expectation, anxiety attacks proper, rudimentary anxiety attacks (e.g., disturbances of heart action, disorders of respiration, sweating, tremors, ravenous hunger, vertigo, vasomotor neurasthenia, paresthesias), pavor nocturnus of adults, certain phobias" This phenomenological description of anxiety still holds true today. At that time, Freud considered that this phenomenon resulted from a transmutation of energy, i e., if there were no capacity for outward expression of impulses (the blocked energy of sexual impulses, for instance), it became converted into anxiety. In subsequent developments of his theory of anxiety, Freud saw anxiety, not as a transmutation of energy of sexual impulses, but as a warning signal to the organism of some kind of danger.

In the face of a situation of danger, one experiences a state characterized by psychological and physiological features, a sense of dread and foreboding, and the many physiological responses related to reactions of the vegetative nervous system. Cannon described these physiological responses as preparing the organism for action in either fight or flight at a time of danger. This, of course, is a necessary, healthy, warning and alerting response. When, however, the response is greater than the external danger seems to require and when the response occurs without the presence of an apparent external danger, there exists an anxiety reaction with pathological implications Frequently, such anxiety occurs in the face of an individual's internal psychological conflict over impulses and thoughts which are psychologically unacceptable to him. When an apparent external danger is present, the response is usually designated as *fear;* when the response is disproportionate to the external danger or occurs without the presence of an obvious external danger it is designated as *anxiety.* The actual psychophysiological responses of fear and anxiety are difficult to differentiate.

Individuals vary in the way in which they experience anxiety. Anxiety may be represented by parts of the total psychophysiological phenomenon "Anxiety in the adult activates certain visceral patterns which are specific to the individual, no matter what the stress. Each one has his particular way of feeling anxious Some variations include sinking abdominal sensations, diarrhea, vomiting, dyspnea, sensation of a lump in the throat, etc. Out of the generalized infantile precursors of anxiety, each person seems to have been conditioned to certain fragmentary visceral patterns which for him become accurate and faithful harbingers of intra-psychic danger" (Grinker and Robbins). In the light of this, it can be seen where cardiorespiratory symptoms can be representative of anxiety in a particular individual. Either these symptoms, cardiac and respiratory, may be the only representatives of anxiety or they may be the only evident ones, depending on the particular inclinations of the observer

Anxiety is recognized as being common to all the neuroses. The particular neurotic reaction, in fact, is considered to be the resultant of the types of psychological defense used to ward off the experiences of anxiety. An individual may experience episodes of anxiety as such and thus be suffering from an anxiety neurosis. Development of defenses against such an experience, varying with the types of defense, may result in such neurotic reactions as phobias, hysterical conversions, obsessive-compulsive neurosis, depression, and hypochondriacal reactions. In any of these conditions, there may be an array of symptoms which would meet the criteria of "neurocirculatory asthenia"

Psychogenic Factors and Constitutional Factors. Miles and Cobb emphasize multiple causative factors in disease, i.e, any particular disease state may be the result of the interplay of factors which they call (1) genogenic-hereditary, (2) chemogenic, (3) histogenic-structural, and (4) psychogenic In the case of neurocirculatory asthenia, they consider a continuum, at one end of which are those cases primarily due to, for instance, genogenic and chemogenic factors. those patients who have evidence of a constitutional physiological deficit; and, at the other end of the continuum, those instances wherein psychogenesis is primary. Most patients fall between the extremes

able psychotherapeutic help without referring the patient to a psychiatrist. In this group of patients, when they are confronted with acute stressful situations, handling of the problem as was suggested above can often help the patient to reach a more satisfactory level of functioning Some cases may require continuous emotional support which can be effected by periodic visits to the physician.

There are other cases which require referral to a psychiatrist. In some patients, who have been relatively intact psychologically prior to an acute stress, the reaction to stress may be of such intensity that the therapy requires the services of a psychiatric specialist The degree of psychopathology in many of the chronic cases may be such that handling of the acute problem or emotional support by the physician is not sufficient and the services of a psychiatrist are required.

Symptomatic therapy can be considered secondary but important in the handling of these cases This includes such measures as the judicious use of sedation, rest, and occupational therapy.

CARDIOVASCULAR DISORDERS OF PSYCHOTIC PATIENTS

The syndrome described and discussed in the earlier part of this chapter can occur in psychotic patients as well as in patients with various types of neurotic disorders and character disorders Anxiety and defenses against anxiety are at the center of all psychopathological phenomena, neurotic and psychotic The type of psychological defense used by the individual in order to avoid the experience of anxiety determines the type of pathological manifestations

Patients who are psychotic, neurotic, or "normal" can all, at various times, experience anxiety, which, as previously stated, can be represented mainly by cardiovascular manifestations Some psychotic patients are particularly vulnerable to the development of anxiety, because [illegible] def[illegible] [illegible] threatening to them

Certain features of the psychological defense manifestations in psychotic patients determine the character of the cardiovascular complaints found in such patients. The features of interest include the psychotic's break with reality, turning of interest from other people and things to oneself and one's body, delusions, and hallucinations (Fenichel). Somewhat schematically stated, the psychotic patient, being unable to integrate his feelings and impulses with the real world of people and things breaks with reality, withdraws into himself and, at times, substitutes for reality false thoughts, delusions, and false perceptions, hallucinations

Of particular clinical interest is the observation that at times a schizophrenic patient in the process of breaking with reality may present himself to his physician, preoccupied with bodily complaints. Along with any other system or part of the body, the cardiovascular system may be the focus of such complaints Having broken with reality and thereby being in a state with faulty "reality testing," the patient might elaborate otherwise insignificant bodily sensations into complaints which to the patient have the implication of somatic pathology A more or less tenacious hypochondriacal concern with bodily parts and functions may characterize the schizophrenic patient in the early phases of his break with reality, or, for that matter, at any stage of the disease process The complaints may take on the character of *somatic delusion* These may consist of complaints which are more or less obviously bizarre in nature At times, the exact content of the patient's thought may be somewhat difficult to obtain The patient, for instance, might present the idea that he must breathe in some peculiar manner and rhythm lest something happen to him, other people, or the world, or he might have such notions as that his heart is shriveling or breaking open or that his heart is in some bizarre location in his body Particularly important is that the physician be aware that *early manifestations of a schizophrenic breakdown may be characterized by the patient's preoccupation with somatic complaints*

There are reports in the literature on the relationship between psychoses and psychosomatic disorders (cf. summary of this subject by Ross, review of literature of the relationship between cardiovascular manifestations of a psychosomatic nature and psychoses by Miller and by Swartz and Semrad). There are studies that appear to indicate that psy-

the presenting symptomatology and the severity of the organic heart disease. The diagnosis, however, is not only by exclusion but by alertness to positive data supporting the psychological basis of the symptomatology. The decision to refer a patient to a psychiatrist for examination depends upon the training and ability of the physician in attendance, i.e., his awareness of, alertness to, and ability to handle psychological factors in disease.

The differentiation of this disorder from various medical illnesses is at times a problem. Patients at times may receive the diagnosis of tuberculosis, thyroid disease, cardiac disease including angina pectoris, "murmur," rheumatic fever, sinusitis, undulant fever, and, if the symptoms involve other systems, Ménière's disease, peptic ulcer or gastric neurosis, genitourinary disorders, or disorders of the nervous system

THERAPY

Therapeutic approaches to this disorder must be based on correct diagnosis and understanding. It is important to assess (1) constitutional (physiologic) mechanisms, i.e., patients with lifelong "low effort tolerance"; (2) long-standing psychological difficulties (that is, patients with a chronic psychological disorder who have a propensity for the development of anxiety and cardiovascular symptoms), (3) patients who up to the time of onset of symptoms have been relatively intact physiologically and psychologically but who have been confronted with a rather acute, stressful psychological experience with the development of anxiety and psychological defenses against this anxiety. Physiological, psychological, and environmental factors must be considered

In all cases, the physician must be aware that his initial and subsequent handling of the case can determine whether the patient is directed to the road to recovery or whether there is a tendency for the disorder to become fixed, intractable, and chronic. In other words, "*iatrogenic*" *factors* can foster neuroticism, which, in this instance, is manifested by cardiorespiratory symptoms A thorough history must be taken and a complete examination performed. Following this, the physician must, without equivocation, inform the patient that he has no organic cardiac disease, that he has an "emotional disorder" and that his heart is normal and there is no reason why anything should happen to it. It is very important not to give the patient the impression that, by making such a diagnosis, one considers him a second-rate individual and looks down on him. The therapy should not be complicated by giving the disorder a name which serves no purpose but to arouse the patient's anxiety and really does not explain the nature of the situation The physician's understanding and interest in the patient's symptoms should be communicated in the physician's words and manner.

Recommendation of *rest* should be very judiciously made, lest one foster a chronic neurotic withdrawal from a constructive solution of whatever problems have brought about the symptoms.

When constitutional-physiologic predispositions to the development of symptoms can be discerned, one has to consider with the patient the establishment of a regimen of activity which diminishes the stress to his physiological mechanisms.

It is in regard to psychogenic factors that more definitive therapeutic approaches can be made In those cases where it is apparent that there is a relationship between acute psychological stress and the development of symptoms, it is by no means necessary to refer all such patients to psychiatrists The nonpsychiatric physician can perform effective and important psychotherapy commensurate with his experience, interest, and effort toward doing so A patient who is struggling with a recent psychologically stressful situation can gain much from the doctor-patient relationship· (1) from the emotional support which derives from the very existence of such a relationship, giving someone with whom the patient can talk, (2) from intellectual support offering help in the clarification of the problems that confront him and a presentation of possible ways of solving them; (3) from an opportunity to ventilate his feelings about the matter; (4) from suitable environmental changes when they are indicated; and (5) from the opportunity to reinstate previous psychological defenses or, when possible, to reach a satisfactory, constructive solution of the problem.

In cases where there have been long-standing neurotic or psychotic difficulties, the nonpsychiatrist, again, can often be of consider-

able psychotherapeutic help without referring the patient to a psychiatrist In this group of patients, when they are confronted with acute stressful situations, handling of the problem as was suggested above can often help the patient to reach a more satisfactory level of functioning Some cases may require continuous emotional support which can be effected by periodic visits to the physician.

There are other cases which require referral to a psychiatrist In some patients, who have been relatively intact psychologically prior to an acute stress, the reaction to stress may be of such intensity that the therapy requires the services of a psychiatric specialist The degree of psychopathology in many of the chronic cases may be such that handling of the acute problem or emotional support by the physician is not sufficient and the services of a psychiatrist are required

Symptomatic therapy can be considered secondary but important in the handling of these cases This includes such measures as the judicious use of sedation, rest, and occupational therapy

CARDIOVASCULAR DISORDERS OF PSYCHOTIC PATIENTS

The syndrome described and discussed in the earlier part of this chapter can occur in psychotic patients as well as in patients with various types of neurotic disorders and character disorders Anxiety and defenses against anxiety are at the center of all psychopathological phenomena, neurotic and psychotic The type of psychological defense used by the individual in order to avoid the experience of anxiety determines the type of pathological manifestations.

Patients who are psychotic, neurotic, or "normal" can all, at various times, experience anxiety, which, as previously stated, can be represented mainly by cardiovascular manifestations Some psychotic patients are particularly vulnerable to the development of anxiety, because, in the face of inadequate psychological defenses, they are repeatedly encountering situations which are socially or psychologically threatening to them.

Certain features of the psychological defense manifestations in psychotic patients determine the character of the cardiovascular complaints found in such patients. The features of interest include the psychotic's break with reality, turning of interest from other people and things to oneself and one's body, delusions, and hallucinations (Fenichel). Somewhat schematically stated, the psychotic patient, being unable to integrate his feelings and impulses with the real world of people and things breaks with reality, withdraws into himself and, at times, substitutes for reality false thoughts, delusions, and false perceptions, hallucinations

Of particular clinical interest is the observation that at times a schizophrenic patient in the process of breaking with reality may present himself to his physician, preoccupied with bodily complaints Along with any other system or part of the body, the cardiovascular system may be the focus of such complaints. Having broken with reality and thereby being in a state with faulty "reality testing," the patient might elaborate otherwise insignificant bodily sensations into complaints which to the patient have the implication of somatic pathology A more or less tenacious hypochondriacal concern with bodily parts and functions may characterize the schizophrenic patient in the early phases of his break with reality, or, for that matter, at any stage of the disease process The complaints may take on the character of *somatic delusion*. These may consist of complaints which are more or less obviously bizarre in nature At times, the exact content of the patient's thought may be somewhat difficult to obtain The patient, for instance, might present the idea that he must breathe in some peculiar manner and rhythm lest something happen to him, other people, or the world, or he might have such notions as that his heart is shriveling or breaking open or that his heart is in some bizarre location in his body. Particularly important is that the physician be aware that *early manifestations of a schizophrenic breakdown may be characterized by the patient's preoccupation with somatic complaints*

There are reports in the literature on the relationship between psychoses and psychosomatic disorders (cf summary of this subject by Ross; review of literature of the relationship between cardiovascular manifestations of a psychosomatic nature and psychoses by Miller and by Swartz and Semrad) There are studies that appear to indicate that psy-

choses and psychosomatic disorders tend not to exist together. Perhaps the best evidence of this nature has been presented in relation to asthma and peptic ulcer. In the realm of cardiovascular manifestations, a fair amount of attention has been given to the relationship between *blood pressure levels in psychotic patients* and a possible higher incidence of *rheumatic heart disease in "dementia praecox" patients.* The resultant of the several studies on blood pressure levels seems to indicate that elevated blood pressure is probably no less frequent in mental hospitals than in outside medical practice. Some studies, however, seem to indicate that schizophrenic patients tend to have *lower* blood pressure levels than do control subjects. This lower blood pressure level seems to be especially true of catatonic patients. Psychotic epileptics seem to be free from hypertension. There appears to be evidence for elevated blood pressure correlated with depressive and paranoid trends, apparently related to the inhibited aggression which characterizes these clinical states (Miller).

It must be emphasized, of course, that structural cardiac disease can exist in psychotic patients along with the possible disorders described above.

PART 18

Heart failure; Pulmonary edema

1

Experimental heart failure

WILLIAM F. HAMILTON

"Congestive failure" of the circulation is common in clinical medicine and growing more common. In veterinary medicine it is less common but is being recognized with greater frequency in dogs, particularly in spaniels Only recently has it been produced experimentally

THE REGULATIONS OF THE NORMAL CIRCULATION

In order to understand the mechanism of congestive failure, it is necessary to understand how the circulation is regulated and how the sequelae of cardiac weakness, valvular disorder, or overwork may give rise to the manifestations of pulmonary and systemic congestion which are known as "congestive failure" It is further necessary to outline how these manifestations are to be produced and modified experimentally

The circulation seems to be regulated by the peripheral arterioles rather than by the heart, the heart acting as the pump in the water works of a city, which keeps constant the pressure in the distributing system It is only when the well runs dry that the filling of the pump assumes critical importance In the normal circulation, the heart is supplied with venous blood in ample measure and by ingenious contrivance, so that it may pump twenty times the normal resting output and forty times that [illegible]

[illegible] To be specific, when a muscle becomes active, local mechanisms cause its blood vessels to dilate Again, when the room is warm, the skin arteries dilate reflexly. The resulting drop in blood pressure whips up the rate and the strength of the heart by way of reflexes which originate in the carotid sinus and the aortic arch These reflexes do not cause the heart to overdo because, when the blood pressure gets back to normal, these same reflexes put the brakes on the heart and open up arteriolar safety valves. In short, the cardiovascular regulation is engineered to maintain a constant distributing pressure no matter what the local demands may be.

The manner in which the heart does the increased pumping that serves increased activity is interesting and, in describing it, the author must break with tradition If the size of the dog's heart is measured radiographically in a carefully quantitated fashion it is determined (Hamilton et al, 1950, a, b), that, as it pumps harder and faster, it grows smaller The only clear correlation between heart size and any other cardiac function including stroke work, stroke volume, and venous pressure, *is between heart size and heart rate.* The faster it goes, the smaller it becomes In general, the faster it goes, the more work it does

At first glance, it would seem that this contradicts the classical principle of Starling's law of the heart This is not so Starling's principle (Part 2, Chap 6) was stated for conditions which rule out reflex and hormonal regulation Starling devised the heart-lung preparation so that these influences would surely be ruled out and came to the conclusion that, when the heart is considered as a simple isolated muscle, its pumping energies and its metabolism vary directly with its diastolic size. The more distended the heart, the more strongly it pumps and the more energy it releases However, if the heart is overdistended, the gain becomes a loss and the pumping weakens

The difference between the behavior of the heart in the normal animal and in the heart-lung preparation is, of course, the result of reflex and hormonal adjustments that protect the natural heart from the stress of dilatation, and the fact that the natural heart has a large volume of residual blood in its

cavities and can increase its stroke by *emptying* more completely as an alternate to filling to a greater diastolic size.

The fact that the natural heart is reduced in diastolic size under stress and differs in this respect from the isolated heart of Starling has been documented for the dog heart during exercise by Rushmer (1952, 1954) and for the human heart by Liljenstrand et al who showed that the heart of the individual when supine was larger than when he was doing exercise.

It is, of course, well known to clinicians that the *diseased heart* dilates and thus gains strength in accordance with the Starling principle. If the *dilatation is too great, the heart loses strength, again* in accordance with Starling's principle. This dilatation, however, is a mechanism of last resort, used only when reflex and hormonal adjustments have failed. The diseased heart meets stress by increasing its diastolic size, the normal heart by diminishing its systolic size This is done by reflex augmentation of the rate and strength of the contraction.

The only application of Starling's law that can clearly be made to the heart with all of its natural reflex controls was clearly put forth by *Henderson* and Prince long before Starling The two ventricles are, of course, controlled by the *same mechanisms* and neither can be stimulated separately by either reflex or hormonal agencies. The only way that either can carry an extra load or overcome an extra handicap is by gaining strength through the Blix-Starling mechanism, that is, by dilating to a greater diastolic size Henderson and Prince by ingenious experimentation showed that the filling and response curves of the two ventricles safeguarded the pulmonary circulation from being either depleted *or distended.*

CAUSES OF CONGESTIVE FAILURE

Backward Failure. In the pulmonary circulation within physiological limits, the above-described adjustment works very efficiently. *We all know, however, that, with pathological* handicap to the left ventricle, the needfully *perfect balance between the outputs of the* right and left ventricles can be preserved only at the expense of an abnormally high left atrial (and intrapulmonary vascular) pressure, the pressure that fills the left ventricle

The development of this high pulmonary vascular pressure leads to many of the clinical aspects of heart disease. The lungs become engorged and stiffer, so that the work of breathing is increased and respiration becomes dyspneic. Blood in the dilated heart and engorged lungs encroaches on the pulmonary air space and reduces the vital capacity. This blood increases the circulation time, and its pres may cause incipient pulmonary edema with familiar "moist rales."

This condition can be produced experi tally but, so far as the author knows, it n appears as a chronic condition in experime animals. Any condition which puts a suffi strain on the left heart will increase the i vascular pressure in the lungs. A typical *is an overdose of epinephrine.* Both pulmo arterial and pulmonary venous pressures alike and the difference between them les *There is no evidence of* pulmonary vaso striction, even when the drug has pa through the lungs on its first circulation. same dose of drug with nearly the same fect on the systemic pressure can be g with no rise in pulmonary pressure if the mal has suffered hemorrhage. The au thinks that, ruling out possible action on lung of irritant gases, pulmonary edema i ways due to the fundamental mechanism i trated here. The picture is one of a weake or overwhelmed left ventricle, back pressu the lungs, and filtration through the capilla and the condition can often be amelioratec venesection or by other measures, e g , v dilator drugs designed to reduce the load the left ventricle or lessen its effects, or the of alcohol fumes to lessen frothing of the ed fluid (Luisada, 1950).

Backward Failure in the Systemic Circ tion. There is doubt in the minds of phys gists that backward failure of the right h can occur, whether it is consequent to heart failure or is the result of initial inc petence of the right heart After epineph the systemic venous pressure changes slightly, even though the pulmonary vasc pressures are high and the left ventricle fers an acute dilatation. In contrast to pulmonary bed, the systemic bed is very pacious, particularly as to its venous port in order to distend it a large increase in bl volume is necessary. In addition, the heart self is dilated and contains a greatly increa amount of blood as compared to its nor state Not only are the blood volume venous pressure increased, conditions wh persist post-mortem, but also there is a g increase in the interstitial fluid volume.

This plethora and dropsy can only be

plained on the basis that there has been a long-standing imbalance between the intake and output of salt and water. The kidney is the organ controlling the output of salt and water and it seems clear that the fault lies in this organ

The kidney may retain salt and water in amounts to form edema for any of three causes: (1) deviation of fluid into the interstitial spaces before it can get to the kidney; (2) alteration in renal hemodynamics so that filtration is so small that resorption of filtered sodium and water occurs, and (3) augmentation of tubular resorption of sodium and water by hormonal or other stimulation.

Prerenal deviation due to high venous pressure is the traditional explanation for edema As seen above, the initial stages in the rise of venous pressure cannot be explained in this manner Nor is there any necessary correlation between the development of edema and the level of venous pressure. Altschule and Blumgart believe that, in tricuspid stenosis, venous pressure is elevated without edema, and Altschule (1954) indicates that, particularly in mitral stenosis, edema may develop with normal venous pressures Merrill (1949) finds that edema precedes the rise in venous pressure as heart failure develops, though this has been questioned

The causal relation of high venous pressure to experimental ascites is moot. Davis et al (1953, 1955) believe that ascites develops only when the pressure of the inferior vena cava is high Others report ascites in the absence of signs of chronic passive congestion and with the pressure of the inferior vena cava exceeding the (high) intraabdominal pressures There seems to be an equivocal relation between ascites and high venous pressure in experimental tricuspid stenosis and Waugh has shown that, during the onset of ascites from vena cava constriction, 10 days elapse, in which the caval pressure is high, before ascites develops. The trigger seems to be the exudation into the abdomen of a small amount of ascitic fluid of high protein content. Ascitic fluid in the dog has a protein content 1 to 1 5 per cent lower than plasma while, in man, the difference is much greater Barger finds significant sodium retention in animals who have received slight valvular damage, this was not sufficient to produce a rise in venous pressure, even though the pressure was high when frank congestive failure developed.

This equivocal relation between edema production and venous pressure is to be expected on physiological grounds There is a perfect balance between outward filtration at the arteriolar end of the capillary and inward diffusion at the venous end of the capillary but this is precarious and can be upset by very small changes in venous pressure (even by drinking a glass of water, which passes out through the capillary with infinitesimal changes in venous and osmotic pressures).

These considerations lead to the thought that *the rise in venous pressure is coincident with edema rather than its cause,* and to look elsewhere for the underlying basis. It is well known that, in nephrotic episodes, oliguria will lead to edema and that for unknown causes this may be followed by diuresis and evacuation of edema with no change in venous pressure Similarly, bed rest may cause diuresis in cardiac patients with no lowering of venous pressure. This and other evidence points to the causal role of a possible upset in renal function in the edema of heart failure.

Renal Function and Edema Production. Renal function may be disturbed in heart failure by a simple change in renal hemodynamics or by a stimulation of tubular resorption Merrill showed that glomerular filtration was greatly reduced in congestive failure He thought that the small amount of filtrate was nearly cleared of sodium and water by the obligate function of the proximal tubule Against this is the fact that, when patients come out of decompensation, they usually do so with a continued low filtration rate, such changes as do occur being random; this fact has been confirmed by many workers In experimental animals, it has been shown that circulatory handicap may result in increased reabsorption of sodium and water with filtration remaining within normal limits This is true temporarily when the renal vein is constricted, and permanently when the inferior thoracic vena cava is constricted, or when a dog is affected with mitral, pulmonic, or tricuspid stenosis

Stimulation of Tubular Resorption. It seems doubtful from the above that the edema of heart failure can be explained as the result

of prerenal deviation of fluid or as a result of changes in renal hemodynamics. It remains, therefore, to inquire into the possibility that *the salt and water are retained as a result of overstimulating the tubular resorptive function.* Raising the pressure in one renal vein causes a unilateral increase in tubular resorption of these substances with no other changes in renal function or capacity. However, since this is only a temporary response and does not lead to ascites, the permanent ascites which results from the other, above-mentioned handicaps requires further analysis.

Since the last century, clinicians have known that *a low-salt diet was good for dropsical patients.* The ascites of experimental circulatory handicap is also dependent upon sodium. This ion can be withheld from an ascitic dog either by the careful control of the diet or, much more conveniently, by the use of ion exchange resins (Carbo-resin). When sodium is withheld for a few days, a diuresis sets in and the ascitic fluid is promptly evacuated. The animals can be kept apparently normal for weeks under this treatment, only to regain their ascites as soon as a normal diet is reinstituted.

It is also recognized clinically that the *withholding of water is not helpful in treating cardiac dropsy.* Nonetheless, the rarity of cases of diabetes insipidus with congestive failure leads one to wonder if the two diseases are not incompatible and whether water might not be retained, holding sodium, by means of the antidiuretic hormone In order to test this, Waugh produced diabetes insipidus in a number of dogs by the usual operation. Some were ascitic in spite of the fact that they were urinating four to ten times the normal volume In others, the circulatory handicap produced ascites even in the presence of well-established diabetes insipidus.

Adrenal Hormone. An important step in the further analysis was taken by Davis (1953), who showed that the ascites which resulted from inferior vena cava constriction could be aborted or evacuated by *adrenalectomy* The stimulus which caused the kidney to avidly resorb sodium was evidently secreted by the adrenal gland since removal of this gland promoted loss of retained fluid. The substance secreted by the adrenal (probably *aldosterone*) was no longer available and had to be replaced by administration of either a high-salt diet or DCA or other salt-retaining sterones, in order to maintain salt balance.

These observations were extended (Hamilton, 1954) to the ascites following experimental mitral stenosis and to that following experimental tricuspid stenosis (Brown et al, 1956). The same observations were made in experimental pulmonary stenosis (Davis et al, 1955) and it was shown that the strength of the right ventricular beat, the cardiac output, venous pressure, and renal functions, were restored toward normal by digitalis. This last observation makes it clear that the main action of digitalis on the dilated heart is to strengthen the myocardium, in spite of the fact that it interferes with pumping in the normal heart.

If aldosterone causes the kidney to retain salt and water to form cardiac ascites in the dog, and by inference edema fluid in man, the question remains. what is the stimulus which produces this activity in the adrenal gland? This is indeed puzzling. The administration of the cortisone-producing pituitary hormone (ACTH) or of cortisone itself, will not cause any significant retention of salt or water in dogs (Howell et al., 1955). Hypophysectomized dogs respond normally to feeding excess salt and to withholding salt, but not to circulatory handicap Thus Craig and Wetzel, as well as Davis, and Waugh and Hamilton, have shown that ascitic dogs promptly lose ascitic fluid when the pituitary gland is removed The identity of the stimulus which causes the pituitary-adrenal complex to become active in response to circulatory handicap remains to be seen.

To summarize this review on experimental congestive failure of the circulation, it would seem that simple backward failure of the left ventricle is an adequate description of the pulmonary congestion which accompanies the disease but the retention on the systemic side of the circulation of intravascular and extravascular fluid, together with the rise in venous pressure, is much more complex. Renal retention of salt and water is a necessary step in the mechanism This retention is not the simple consequence of low filtration but must also involve stimulation of tubular resorption of salt and water which is probably hormonal The antidiuretic hormone of the posterior pituitary gland does not seem to be involved in

the production of ascites The adrenal gland plays an important role in the vicious cycle, as does, in all probability, the anterior pituitary. The actual mechanism of the initial stimulus and many of the connecting links are unknown

The biological meaning of this response is puzzling It cannot be a homeostatic response since the retention of water and sodium by an organism already inundated by salt water is hardly a regulatory response. It is better to regard it as a response which meets adequately an acute emergency but is badly adjusted to a chronic diseased state The conservation of body fluid and sodium is easily recognized as important in preparation for the violent activity displayed in meeting an emergency. Heat can be liberated, and the circulation maintained, if fluid is in adequate supply. Moreover sweat involves the loss of salt and anoxic or traumatic cell damage, an escape of potassium into the extracellular fluid compartment. Since aldosterone has the effect of conserving sodium, and with it water, as well as releasing potassium, Meneely suggested that its emergency secretion fits neatly into the biological picture Its continuous secretion in a chronic disease that simulates an emergency situation can thus be explained on Darwinian grounds even though it is not homeostatic.

of prerenal deviation of fluid or as a result of changes in renal hemodynamics It remains, therefore, to inquire into the possibility that *the salt and water are retained as a result of overstimulating the tubular resorptive function.* Raising the pressure in one renal vein causes a unilateral increase in tubular resorption of these substances with no other changes in renal function or capacity. Since aldosterone has the effect of conserving sodium, and with it water, as well as releasing potassium, Meneely suggested that its emergency secretion fits neatly into the biological picture. Its continuous secretion in a chronic disease that simulates an emergency situation can thus be explained on Darwinian grounds even though it is not homeostatic

Cardiac output and venous return in heart failure

ARTHUR C. GUYTON

Because the term "heart failure" can be defined in several different ways, it is impossible to discuss cardiac output and venous return during failure without first defining the term as it will be used in this chapter. One definition of heart failure is simply that *the heart fails to pump all the blood returning to it from the systemic circulation* According to this definition, the heart itself may be perfectly normal but still cannot pump all the blood simply because flow through the systemic circulation is unusually rapid (*relative heart failure*). Another definition of heart failure is that *the actual pumping effectiveness of the heart has been impaired* (*absolute heart failure*) The present discussion will employ this latter definition However, later in the chapter, the factors that cause high cardiac output in "high output failure," in which the heart itself is either completely or nearly normal, will be discussed separately.

QUANTITATION OF FAILURE

One cannot determine how severely the heart is failing by simply measuring the cardiac output because, even a normal heart which does not receive an adequate venous return of blood, may pump only a few milliliters of blood per minute. In this instance, the heart would not be failing in the least. On the other hand, it is not possible to quantitate the degree of heart failure by simply measuring the venous pressure because the venous pressure can be elevated even in the presence of a normal heart if blood is flowing into it at an excessive rate Consequently, to quantitate the degree of failure, one must speak in terms of the ability of the heart to pump blood at many different right atrial pressures (Sarnoff).

Figure 18-1A illustrates function curves called "cardiac output curves" which depict the pumping ability of a normal heart and of hearts whose pumping effectiveness has been depressed 25 per cent, 50 per cent, and 75 per cent, respectively. This graph depicts the amount of cardiac output which could be expected from the respective hearts at each right atrial pressure In the normal heart the cardiac output at each right atrial pressure is greater than that of any of the failing hearts. The heart that has lost 25 per cent of its pumping effectiveness will pump only approximately 75 per cent as much blood at each right atrial pressure as that pumped by the normal heart Correspondingly, the hearts that are failing 50 and 75 per cent pump only one-half and one-fourth as much blood as does the normal heart at each given right atrial pressure. Thus it can be seen that the degree of cardiac failure can be quantitated by means of cardiac output curves Conversely, one can estimate the degree of failure of a given heart if both the cardiac output and right atrial pressure are simultaneously recorded. For instance, if a person's resting cardiac output is 5 liters/min and his right atrial pressure is 0 mm Hg, then the point described by these coordinates in Fig 18-1A lies on the curve of the normal heart, which means that his heart is operating normally On the other hand, if the cardiac output is 1 25 liters/min but the right atrial pressure is 0 mm Hg, this point lies on the fourth curve; this means that the heart is failing approximately 75 per cent despite the normal venous pressure.

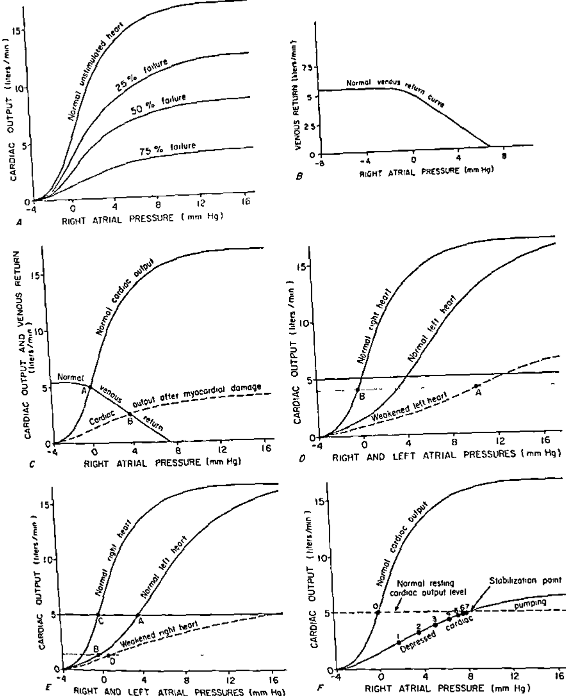

Fig 18-1. A Cardiac output curves for the normal heart and for hearts with 25 per cent, 50 per cent, and 75 per cent failure, respectively B A normal venous return curve C. Method of equating a venous return curve with a cardiac output curve, and the effect of myocardial damage on cardiac output and venous return. D Cardiac output curves for the normal right heart, the normal left heart, and a weakened left heart, illustrating the effect of a weakened left heart on cardiac output, right atrial pressure, and left atrial pressure E Cardiac output curves for the normal left heart, the normal right heart, and a weakened right heart, illustrating the effect of a weakened right heart on cardiac output and right and left atrial pressures F Cardiac output curves for a normal heart and for the same heart immediately after the pumping efficiency of the heart has been markedly decreased. This figure illustrates the increases in cardiac output and right atrial pressure on successive days after the acute depression of the heart.

It should also be noted that the failing heart can often pump a normal cardiac output provided the right atrial pressure is high enough. The third curve of Fig. 18-1B illustrates a heart that has lost 50 per cent of its pumping effectiveness but, still, when the right atrial pressure rises to approximately 2.4 mm Hg, the cardiac output becomes essentially normal. However, exercise and other cardiac stimulants fail to raise the cardiac output as much as usual because the heart, even under resting conditions, is already pumping blood almost as rapidly as it can. In other words, a greatly weakened heart, when primed sufficiently with inflowing venous blood, can often pump the same amount of blood per minute under resting conditions as can the normal heart, but the *cardiac reserve* is greatly diminished.

REGULATION OF CARDIAC OUTPUT AND VENOUS RETURN IN FAILURE

The amount of blood pumped by the heart each minute is not determined only by the ability of the heart to pump blood, for the rate at which blood returns to the heart from the veins is also a determining factor. In other words, cardiac output is determined by both (1) the effectiveness of the heart as a pump and (2) the tendency for blood to flow from the veins into the heart. The effectiveness of the heart as a pump can be quantitated by use of cardiac output curves as described above, while the tendency for blood to return from the veins can be depicted by "venous return curves" (Guyton, 1955 and 1956) (Fig. 18-1B). The important points of these curves may be described as follows.

Factors that Affect Venous Return. RIGHT ATRIAL PRESSURE. The curve of Fig 18-1B illustrates the effect on venous return of changing the right atrial pressure. When the right atrial pressure is less than 0 with respect to the atmosphere, the veins entering the thoracic cavity collapse, this prevents the negative pressures of the chest from sucking blood into the heart (Part 2). Therefore, the amount of blood that returns to the heart remains almost constant at all right atrial pressures lower than 0 mm Hg. On the other hand, when the right atrial pressure rises above 0, the pressure backs up into the peripheral veins, distending them and slowing down the flow of blood toward the heart. In the normal animal with normal vasomotor tone throughout its body, a rise of right atrial pressure to 7 mm Hg stops the flow of blood to the heart entirely (Guyton et al, 1954b). Obviously this decrease in venous return to zero makes the mean arterial pressure fall down to 7 mm Hg at the same time that the venous pressure is rising up to this value.

Application of the principles shown in Fig 18-1B to heart failure are obvious, for decreased pumping effectiveness of the heart normally increases the right atrial pressure, and this in turn depresses the venous return If the heart's pumping ability is only slightly impaired, excessive fall in venous return may be prevented by the compensatory effects of increasing vasomotor tone and increasing blood volume, which will be discussed later. But when the pumping effectiveness is decreased to a very great extent, each additional rise in right atrial pressure can no longer be compensated, and the venous return may fall disastrously, as much as 14 per cent for each mm Hg rise in right atrial pressure.

EFFECT OF BLOOD AND INTERSTITIAL FLUID VOLUMES ON VENOUS RETURN. Increasing the blood volume raises the blood pressure in each respective vessel throughout the circulation, and, as a result, the venous return correspondingly increases. An increase in interstitial fluid volume also increases the rate of venous return but in a slightly different way. The increased fluid in the interstitial spaces presses against the outside of the vessels, thereby increasing the blood pressure inside the vessels This pressure in turn promotes increased blood flow toward the heart In other words, an increase in either blood volume or interstitial fluid volume can compensate to a considerable extent for depressed cardiac pumping effectiveness. To present this idea in another way, increased blood or interstitial fluid volume increases the tendency for blood to return from the vascular system to the heart, and *even a weakened heart, when primed with increased quantities of inflowing blood, can often pump a normal cardiac output.*

EFFECT OF INCREASED VASOMOTOR TONE ON VENOUS RETURN AND CARDIAC OUTPUT. Increasing the vasomotor tone is another factor which will increase venous return and cardiac output When generalized increase in vasomotor tone occurs *throughout* the circulation, the tightening of each vessel against the enclosed blood increases the pressure, and this forces blood toward the right atrium at an increased rate of flow. One might expect generalized in-

crease in vasomotor tone always to increase the resistance to blood flow toward the heart However, this is not true for the following reason *When* a vessel constricts, it must displace its enclosed blood into some other vessel, but when all vessels attempt to constrict proportionately at the same time, no one vessel can constrict because each of them is trying to displace its blood into the others. The net result is simply an increase in the pressures throughout the circulation without any vasoconstriction. This is the result found experimentally when epinephrine is injected into an animal, and also occurs during generalized sympathetic stimulation Therefore, the amount of blood that returns to the heart from the veins is greatly increased by either epinephrine injection or sympathetic stimulation In this way, then, generalized increase in vasomotor tone, like increased blood volume, *often* compensates for depressed pumping *effectiveness* of the heart

Graphic Method for Analyzing the Equilibrium between Venous Return and Cardiac Output Figure 18-1C illustrates a graphic method by which one can analyze the effect of many different factors simultaneously on cardiac output and venous return In this graph, the two solid curves represent the effect of different levels of right atrial pressure on the normal cardiac output and the normal venous return respectively Note that increasing *the right atrial pressure increases the cardiac output but decreases the venous return* At the right atrial pressure, at which the two curves cross, the cardiac output and the venous return are exactly equal. At any right atrial pressure above this value, the venous return is less than the cardiac output, and at any right atrial pressure less than this value, the venous return is greater than the cardiac output Occasionally, some abnormality occurs which throws venous return and cardiac output temporarily out of equilibrium For instance, a sudden transfusion of blood into the right atrium instantaneously increases the right atrial pressure to a high value. As a result, the cardiac output becomes very great but the venous return very low, which means that the heart is pumping far more blood out of the right atrium than is returning to the [illegible] atrium [illegible] how[illegible] have [illegible] right atrial pressure will have fallen back to a low enough value that venous return once again equals cardiac output *Thus, the balance between cardiac output and venous return is always reestablished within a few heart beats*, and the crossing point of the cardiac output and venous return curves (point *A* on the graph) represents the stabilized levels of cardiac output, venous return, and right atrial pressure.

If any factor should change the ability of the heart to pump blood or should change the tendency for blood to return to the heart, then point A would no longer represent the actual operating conditions For instance, if the pumping effectiveness of the heart should be depressed from the solid curve to the lower dashed curve, then the new cardiac output curve and the venous return curve would cross at point B, the cardiac output now would be about one-half normal and the right atrial pressure would have risen approximately 4 mm Hg This graphical demonstration of the shift in operating conditions from point A to point B, therefore, represents a method for analyzing the effects on the circulation of depressing the pumping effectiveness of the heart from normal to about one-third normal Similar procedures may be used for depicting the effects of increased blood volume, increased peripheral resistance, sympathetic stimulation, and other factors, on the cardiac output, venous return, and right atrial pressure (Guyton, 1955 and 1956)

DYNAMICS OF ACUTE HEART FAILURE

More frequently than not both sides of the heart fail simultaneously, but occasionally one side of the heart fails by itself The present discussion will consider, first, the dynamics of one-sided failure, and then these will be synthesized into the over-all effects of combined failure

Dynamics of Acute Left-sided Failure. Acute failure of the left heart means depressed ability of the left ventricle to pump blood from the pulmonary veins into the aorta *As a consequence*, blood shifts out of the *systemic* circulation into the pulmonary *circulation*, damming up in the entire pulmonary vascular tree The pressures throughout the pulmonary system, especially in the veins, rise while those *in the* systemic circulation, including the *systemic veins*, fall slightly rather than rising

Figure 18-1D illustrates the dynamics of cardiac function in left-sided failure. The dashed curve is the cardiac *output curve* of a failing left heart while the sol[illegible] of the [illegible] [illegible] *output* It can be seen that the normal left heart pumps a cardiac output of 5 liters/min when the left atrial pressure is approximately +4 mm Hg, while the output of the *right* heart is *this* same amount when the right atrial

pressure is 0 mm Hg. When left heart function is acutely depressed, the damming of blood in the pulmonary vessels causes the pulmonary blood volume to increase as much as 100 per cent immediately (Lindsey et al.), which greatly increases the left atrial pressure. Simultaneously, the shift of blood out of the systemic circulation slightly decreases the right atrial pressure. Thus, in the figure, the left atrial pressure rises from 4 to 10 mm Hg (point *A*) while the right atrial pressure falls from 0 to −0.4 mm Hg (point *B*). The great rise in left atrial pressure allows even the weakened left heart to pump approximately 4 liters of blood per minute. Because of the decrease in right atrial pressure, the right ventricle also pumps this same quantity of blood. The dotted horizontal line, therefore, represents the new cardiac output level It is evident from this graph that depression of the ability of the left heart to pump blood greatly increases the pulmonary venous pressure and decreases slightly both the right atrial pressure and cardiac output.

The principal effect of acute left failure, then, may be mainly pulmonary congestion with only slight changes in other cardiovascular functions. However, if the damage to the left ventricle is considerably greater than that illustrated in Fig 18-1D, the cardiac output also may be greatly depressed, sometimes even down to shock levels, but this is always accompanied by extreme pulmonary congestion

Dynamics of Acute Right-sided Failure. When the right side of the heart fails rather than the left, blood is dammed in the systemic vessels, and an insufficient quantity of blood fills the pulmonary system. The quantity of blood in the lungs is diminished by as much as 50 per cent while that in the systemic circulation is correspondingly increased (Lindsey et al.). The main difference between left heart failure and right heart failure is caused by the difference in the capacities of the systemic and pulmonary circulations to store blood. *The venous pressure of the systemic circulation rises only one-tenth as much as that of the pulmonary circulation for each quantity of blood added* Consequently, a relatively small amount of blood shifting into the lungs can cause extreme symptoms of congestion while all the blood that can possibly shift from the lungs into the systemic circulation usually causes no perceptible peripheral congestion. As a result, in acute right failure, shift of blood from the lungs to the systemic circulation causes the right atrial pressure to rise only a very few mm Hg, almost never enough to cause significant signs of peripheral congestion immediately after the failure begins.

Acute right heart failure depresses cardiac output far more drastically than acute left heart failure for the following reason When the right heart fails, the quantity of blood that shifts from the lungs into the systemic circulation is too small to increase the right atrial pressure more than a few millimeters (Hg). This is not enough to compensate significantly for the depressed pumping effectiveness of the right heart. In contrast to this, in left heart failure, enough blood always shifts into the lungs to elevate the left atrial pressure significantly, and this can go a long way toward compensating for the weakness of the left heart.

The dynamics of right heart failure are illustrated in Fig. 18-1E which shows the normal cardiac output curve for the right heart, the normal cardiac output curve for the left heart, and a dashed curve representing the failing right heart. When the right heart fails, blood shifts out of the lungs depressing the left atrial pressure from point *A* to point *B*, and, at the same time, this blood shifts into the systemic circulation raising the right atrial pressure from point *C* to point *D* As a result, the normal cardiac output falls from that represented by the solid horizontal line to that represented by the dotted line through points *B* and *D*

The only clinically significant effect illustrated in this diagram is *the greatly depressed cardiac output,* for the changes in left and right atrial pressures are not sufficient to cause symptoms. Thus, acute right heart failure is characterized especially by low cardiac output but by almost no congestive symptoms

Combined Left- and Right-sided Acute Heart Failure. When both sides of the heart fail acutely at the same time, the heart is unable to pump blood satisfactorily either from the pulmonary veins into the aorta or from the systemic veins to the pulmonary artery One might suspect offhand that this would cause congestion in both the systemic circulation and in the lungs. However, this is not true because, *if the degree of failure in the two sides of the heart is exactly proportional, no blood shifts either from the pulmonary circulation into the systemic circulation or in the opposite direction.* However, cardiac

output is depressed directly in proportion to the degree of cardiac failure—the greater the degree of failure, the greater the depression in cardiac output. Therefore, the net effect of acute, simultaneous depression of both sides of the heart is principally a decrease in cardiac output and venous return but very few if any symptoms of either pulmonary or peripheral congestion. The venous pressures in both the pulmonary and systemic circulations rise slightly because of shift of blood from the arteries and blood reservoirs into the veins but not because of displacement of blood from one of the circulations to the other

FACTORS WHICH COMPENSATE FOR ACUTE FAILURE

Effect of Increased Sympathetic Activity Following Acute Failure. One of the most important immediate compensations for depressed pumping ability of the heart after acute failure *is an increase in the degree of sympathetic activity.* Several reflexes cause this increase, though exactly which is the most important is not completely known First, depressed pumping tendency by the heart tends to depress the arterial pressure, which elicits *the pressoreceptor reflex* and thereby increases the sympathetic tone Second, decreased flow of blood to the carotid and aortic chemoreceptors likewise initiates *sympathetic reflexes* Third, decreasing pressures in the pulmonary arterial tree and rising pressures in the great veins of the chest can at times elicit *sympathetic reflexes* Fourth, depression of blood flow to the brain in some instances initiates *sympathetic impulses* because of ischemia in the vasomotor center Regardless of which of these reflexes is most responsible, it is nevertheless a fact that, immediately after the heart has become weakened, the sympathetic nervous system becomes excessively active In experiments in which the functions of the sympathetic nervous system have been blocked, the animal always succumbs at a degree of cardiac depression far less than that which would be necessary to kill an animal with intact reflexes (Guyton et al., 1954a)

Increase in sympathetic stimulation helps to compensate for depressed cardiac pumping effectiveness in two ways: First, *sympathetic impulses directly stimulate the heart* and make those portions of the myocardium which have not been damaged more active than normal. Second, sympathetic stimulation *increases the venous return.* As explained earlier in this chapter, the generalized increase in vasomotor tone caused by sympathetic activity elevates the respective pressures in each segment of the circulation, and this accelerates blood flow toward the right atrium Thus, the heart is primed sufficiently to increase its output even though it is in a weakened condition

In summary, then, almost immediately after acute heart failure occurs, whether it be acute left-sided failure or acute right-sided failure, the falling cardiac output elicits vasomotor reflexes that can go a long way toward compensating for the weakness of the heart. Indeed, if the heart's pumping ability is depressed no more than 50 per cent, it can be expected that the person will experience nothing more than a momentary state of circulatory depression, because the increase in sympathetic tone can almost entirely compensate for this amount of weakness as long as the subject remains relatively inactive.

The Compensatory Effect of Fluid Retention in Cardiac Failure. In the foregoing discussion of the factors which affect venous return, it was pointed out that an increase in either blood or interstitial fluid volume can increase the venous return. Immediately after acute failure, both of these fluid volumes begin to increase for two reasons: First, the sympathetic reflexes which occur when cardiac output is depressed *are especially prone to constrict the renal vessels,* more so, indeed, than almost any other vessels in the body (Smith) This in turn depresses the urinary output of the kidneys, sometimes even to the extent of anuria. During the ensuing days, the blood volume and interstitial fluid volumes increase, resulting in increased return of blood to the heart. The heart becomes primed with progressively greater and greater quantities of blood until, despite its weakness, it may pump a normal cardiac output after several days of fluid retention.

The second factor which causes fluid retention in heart failure *is the stress mechanism* that causes the adrenocortical glands to secrete salt-retaining hormones, *aldosterone* in particular (Davis et al., 1956). Low cardiac output induces cellular stress through the entire body because of the resultant tissue is-

chemia. This in turn, by means not yet entirely understood, elicits rapid production of the adrenocortical hormones, and these then act on the kidneys to promote salt and water retention. This mechanism, therefore, in addition to the direct effect of low cardiac output on the kidney, *causes the body fluids to increase.*

The effects of fluid retention on cardiac output are illustrated graphically in Fig. 18-1F which shows, from top to bottom, the cardiac output curve of a normal heart and the cardiac output curve of a heart acutely depressed. The normal resting cardiac output is represented by point 0 on the normal curve but, immediately after failure begins, the cardiac output will have fallen to point 1 on the lower curve, and the right atrial pressure will have risen a few millimeters of mercury because of the damming of blood in the veins and also because of reflex vasomotor constriction. During the ensuing few days, retention of fluid causes progressively more and more return of blood to the heart and consequently a progressively rising right atrial pressure. On the second day, the right atrial pressure will have risen to point 2, on the third day, to point 3, and, on the fourth, fifth, sixth, and seventh days, to respectively higher pressures The cardiac output also will have been rising at the same time When sufficient fluid has been retained that the cardiac output has risen back to a normal value (at point 7), the vasomotor reflexes elicited by depressed cardiac output no longer remain active, this allows blood once again to flow through the kidneys at a normal rate. As a result, the anuria or oliguria disappears, though in the meantime the right atrial pressure will have risen to 8 mm Hg.

Thus, the retention of fluid acts as a slowly developing compensatory measure, increasing the cardiac output back toward normal when the heart has been weakened If the degree of failure is slight enough that the cardiac output can rise all the way back to normal, further retention of fluid by the kidneys ceases, and the patient becomes stabilized at this point with a permanently elevated right atrial pressure.

EFFECT OF FLUID RETENTION ON THE SYMPTOMS OF CONGESTION. Even though fluid retention may be beneficial to the cardiac output, it also aggravates the symptoms of pulmonary or peripheral congestion. In the case of primarily left-sided failure, the pressures in the lungs are already elevated, and the pulmonary congestive symptoms obviously are only compounded by the fluid retention. Congestive symptoms in the systemic circulation usually do not occur immediately after acute heart failure, whether it be left or right. However, in right or combined heart failure, the fluid retained during the days following the onset of failure gradually increases the pressures in all the systemic vessels, particularly in the veins, resulting in progressive peripheral venous congestion. Thus, as fluid retention progresses, so also do the peripheral congestive symptoms.

PERIPHERAL EDEMA RESULTING FROM HEART FAILURE. When the right heart begins to fail, whether this be right or combined heart failure, the immediate effect on capillary pressure is probably to decrease rather than to *increase it (Guyton et al, 1952).* The reason for this is that the damming up of blood backwards from the right atrium into the capillaries is more than compensated by the depressed flow of blood from the arteries into the capillaries. *Therefore, peripheral edema normally does not result immediately after an acute heart attack.* However, when the failure passes into the chronic state and is compensated by fluid retention, then the capillary *pressure begins to rise* for two reasons: First, as fluid is retained, it increases the venous blood volume resulting in progressively more and more damming of blood in the capillaries Second, fluid retention usually increases the cardiac output by increasing the venous inflow to the heart. As the output rises, the increasing flow of blood through the arteries to the capillaries also elevates the capillary pressure. Thus, even though the immediate effect after an acute heart attack is not to cause edema, nevertheless, as fluid is retained by the kidneys, the capillary pressure rises progressively and most of the retained fluid then leaks into the tissues, resulting in progressive edema

DYNAMICS OF DECOMPENSATION AND ITS RELATION TO CARDIAC OUTPUT

The term "decompensation," like "heart failure," is beclouded by many different definitions The present discussion will consider decompensation as "that state in which the symptoms of pulmonary and peripheral con-

gestion are progressively increasing and the cardiac output may be falling " Eventually all of these factors progress to the point at which the patient must die unless some treatment is instituted to reverse the progression of symptoms

Figure 18-2A illustrates the dynamics of decompensated heart failure The cardiac output curve of this figure is that of a heart in which pumping ability has been decreased to only 15 to 20 per cent of normal. Immediately after the heart fails, the cardiac output falls approximately to point 1 on the curve At this point, the right atrial pressure is only 4 mm Hg, which is not greatly above normal The low cardiac output, however, initiates fluid retention, as was previously explained. Each day more and more fluid is retained but, because of the tremendous depression of the heart's ability to pump blood, even on the third, fourth, fifth, and sixth days, the cardiac output still will not have risen up to the normal level represented by the dashed line. Consequently, the vasomotor reflexes initiated by low cardiac output remain active, and the output of urine by the kidneys never rises back to normal Fluid continues to be retained even when the cardiac output has risen to as high a volume as the heart can possibly pump, and, in the ensuing days, the seventh, eighth, ninth, and tenth days, still more and more fluid is retained causing

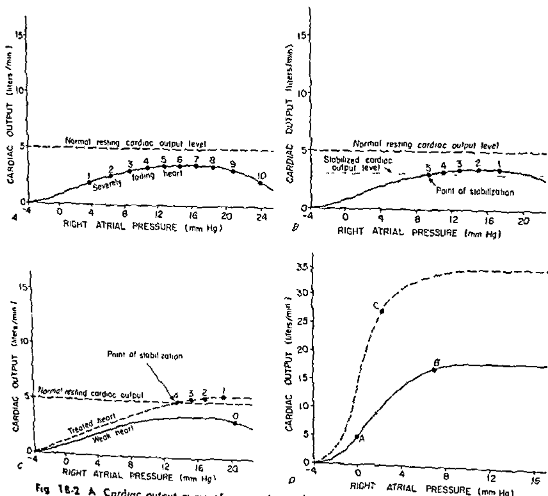

Fig 18-2 A Cardiac output curve of a greatly weakened heart showing the changes in right atrial pressure and cardiac output on successive days after the heart has become acutely weakened. B Compensation of a previously decompensated heart by control of the fluid intake and fluid output (explained in text) C Compensation of a previously decompensated heart by strengthening the myocardium (explained in text) D. Cardiac output curves of a normal heart (solid line) and of a hypertrophied heart (dashed line), showing the effects on the dynamics of cardiac output and right atrial pressure of the greatly enhanced venous return which occurs in high cardiac output failure

more and more edema, more and more peripheral congestion, and eventually the death of the patient.

One of the effects of decompensation is *a terminal decrease in cardiac output.* The exact cause of this has not been completely determined, but it may result from several different factors. First, many physiologists and clinicians have claimed that the main cause might be distention of the heart beyond its normal limits of operation. The effect of this on the cardiac output curve is illustrated in Fig. 18-2A by the decline in the curve at the very high right atrial pressure levels rather than a continuing rise. However, in most experiments on animals this decline is not very extensive. Therefore, it is probable that the final decrease in cardiac output in the decompensated patient is not caused principally by excessive distention of the heart but by other factors. For instance, *edema or ischemia of the myocardium caused by the heart failure could make the heart become even weaker,* thus resulting in more extensive failure with the effect progressing into a vicious cycle of deterioration. Regardless of the exact cause, in the last stages of decompensation the heart goes into a declining phase of function which seems the result of a vicious cycle, the heart getting weaker and this weakness causing still further weakness of the heart until death supervenes

TREATMENT OF DECOMPENSATION

If decompensation has not reached the stage of a vicious cycle of cardiac deterioration, it can often be successfully treated by controlling the patient's fluid balance or by improving the pumping ability of his heart

Figure 18-2B illustrates the effects of treating a decompensated patient by controlling his fluid balance. The usual rate of cardiac output required for the kidneys to maintain normal fluid balance is about 5 liters/min. This level of output is indicated by the dashed line in Fig. 18-2B However, when the patient is placed on a low salt-and-water intake or given a diuretic, the level of cardiac output for maintenance of normal fluid balance might be reduced to as low as 3 liters/min.

In Fig. 18-2B, assume that an untreated patient is in a state of decompensation and that he has reached point 1 on the curve. Then therapy is instituted, so that the cardiac output level required for maintenance of fluid balance is reduced from 5 to 3 liters/min. This is 0 5 liter/min less than the patient's actual cardiac output. Therefore, the fluid output becomes greater than the fluid intake, and the body fluids begin to diminish. The right atrial pressure falls the first day from point 1 to point 2, the second day to point 3, the third day to point 4, and eventually to point 5. In this way the right atrial pressure progressively falls until the cardiac output becomes exactly sufficient to maintain a normal fluid balance. This point of stabilization is point 5 on the graph. The progressive symptoms of decompensation then will have been abated, and the patient will not go on to the vicious cycle of cardiac deterioration.

Treatment of Decompensation by Improvement of Cardiac Function. Figure 18-2C illustrates by the lower cardiac output curve a state of decompensation. Before treatment, the patient has reached point 0 on the curve. Then the patient is treated either by rest therapy or by administration of a drug such as digitalis that increases the effectiveness of cardiac pumping. The result is an increase in the cardiac output curve from the lower solid curve to the upper dashed curve The increased pumping effectiveness immediately lowers the right atrial pressure from point 0 to point 1 and also increases the cardiac output to a rate above the 5 liters/min needed by the kidneys to maintain normal fluid balance. As a result, diuresis occurs and the right atrial pressure falls by the second day to point 2, by the third day to point 3, and by the fourth day to point 4. At this time the cardiac output will have fallen back to the normal value of 5 liters/min at which level the balance between fluid intake and output is reestablished. The patient stabilizes at this point. Thus, the progressive symptoms of decompensation are abated, and the disease does not reach the stage of final cardiac deterioration

In summary, most of the effects of decompensation are initiated by failure of the heart to pump quantities of blood adequate to permit the kidneys to maintain normal fluid balance As a result, progressive fluid retention causes the right atrial pressure to rise, and the symptoms of congestion and edema to increase In the late stages of decompensation the edema, prolonged ischemia (and undoubtedly other factors) cause the pumping ability of the heart to begin to diminish, eventually resulting in a vicious cycle of cardiac deterioration The condition can usually be treated by measures that promote reestablishment of fluid balance. *The two most effective procedures are* (1) treatment of the patient so that the pumping ability of his heart is

increased (by either rest or administration of a glucoside) and (2) salt restriction in the diet, combined with administration of diuretics.

FORWARD VERSUS BACKWARD THEORY OF FAILURE

The terms *forward* and *backward failure* are mentioned in this discussion only for the purpose of explaining their meaning and not to perpetuate their usage in discussions of cardiac failure *Actually, when a heart fails to pump adequately, it both fails to pump blood forward and at the same time dams blood up backwards* Therefore, both effects always occur together, and use of the terms "forward" and "backward" can at times be extremely confusing The meaning of the term "forward failure" is that the symptoms are mainly attributable to diminished cardiac output which, by connotation, is considered to be the "forward" function of the heart. The term "backward failure" means that the symptoms are mainly attributable to the damming of blood behind the heart rather than to diminished output Thus, low cardiac output failure is the same as forward failure, and the symptoms attributable to this are mainly those of ischemia of the different organs of the body For instance, cardiac shock is forward failure On the other hand, backward failure embraces both pulmonary congestion and peripheral congestion. A far better and more physiological description of the different clinical types of failure would be simply the following three basic categories: (1) low output failure, (2) failure with pulmonary congestion, and (3) failure with peripheral congestion Each of these types of failure can occur almost entirely independently of the other two, any two may occur together, or they all may occur simultaneously, depending on which portions of the heart are failing, the degree of failure, and whether or not the failure is acute or chronic.

DYNAMICS OF HIGH CARDIAC OUTPUT FAILURE

High cardiac output failure does not necessarily mean that the heart itself is in a weakened state, but it means instead that the heart is not able to pump all of the blood that is flowing into it from the blood vessels. Indeed, the heart may be completely normal but the amount of blood flowing into it may be so great that even a normal heart is unable to pump it all. Physiologically, this circulatory state should not be considered to be failure of the heart, but some other term, such as *cardiac overloading* should be used to describe it.

The two principal causes of high cardiac output failure are (1) *increased blood volume*, such as occurs immediately after a massive tranfusion or following administration of excess adrenocortical hormones, and (2) *greatly diminished peripheral resistance* allowing very rapid blood flow through the systemic circulation. This occurs in beriberi heart disease, sometimes during excessive exercise, and often in arteriovenous fistulas. In all these conditions, so much blood flows into the right atrium that the heart is *totally unable to cope with it* Much of the blood, therefore, is dammed up in the veins causing symptoms of congestion which simulate those of true heart failure

The dynamics of high cardiac output failure are illustrated in Fig 18-2D. The solid cardiac output curve is that of a normal unstimulated heart, and the normal cardiac output is represented by point *A* If a heart suddenly becomes overloaded by excessive blood flow into the right atrium, the right atrial pressure might rise to 7 mm Hg causing a corresponding increase in cardiac output to 17 liters/min, which is represented by point *B*. The cardiac output remains high as long as the load of blood returning to the heart remains elevated If this state lasts for weeks or more, the excessive work load on the heart causes it to hypertrophy, progressively increasing the ability of the heart to pump blood until its cardiac output curve becomes the one represented by the dashed curve. This increased pumping ability of the heart increases the cardiac output another 10 liters/min from point *B* up to point C, and it lowers the right atrial pressure almost back to normal because the heart can now cope with its excessive load much more effectively than it could immediately after the extra load had first been applied

It is evident then that high cardiac output failure is not failure of the heart at all, but instead is a condition resulting from increased tendency for blood to return from the vessels to the heart. That is, *it is an abnormality of the extracardiac portion of the circulatory system rather than of the heart.*

Metabolic factors of heart failure

PETER TALSO

In the classical considerations of congestive heart failure, the physician has tended to focus his attention primarily on the dynamic aspects, namely, those having to do with the altered dynamics of the heart, with changes in the venous pressure, and with alterations in the hemodynamics of the kidney. Later, however, it was recognized that certain manifestations of congestive failure may be related to metabolic disorders that either develop as a result of failure or may be their prime cause. The present discussion will be limited to a consideration of metabolic changes in the body as a whole while alterations in the intimate metabolism of cardiac muscle will not be considered.

The metabolic aspects of congestive heart failure will be considered in the following order: (1) oxygen consumption or metabolic rate, (2) water metabolism, (3) sodium and chloride metabolism, (4) potassium and nitrogen metabolism, and (5) fat metabolism

METABOLIC RATE

The oxygen consumption of patients in congestive failure has been extensively studied by many workers Perhaps the earliest observations of this kind were those of Peabody and his group, who observed that the "basal oxygen consumption" of patients in congestive failure was considerably higher than that found in normal individuals. Following these observations, an increased oxygen consumption in heart failure has been recorded by many observers More recently, studies of oxygen consumption have been correlated with measurements of protein-bound iodine, of I^{131} uptake, and of radioiodine conversion ratio in patients with heart failure. From studies of this sort, it has been possible to deduce that *the increased metabolic rate observed in congestive heart failure is nonthyroidal in origin and that it is probably due to the increased work demand placed upon the organism as a whole by respiratory distress, by the increased size of the heart, and, perhaps, by other factors such as emotional tension* In some patients with hypertension or rheumatic valvular disease, the basal oxygen consumption has been reported by some to be increased in the absence of frank congestive failure. The mechanism by which this occurs has not been elucidated. The significance of the increased metabolic rate observed in congestive failure and its relationship to the cardiac patient will be discussed below (nitrogen and potassium metabolism)

An increase in oxygen consumption in the presence of a disease state in which *hypoxia* plays a major role seems paradoxical; however, when it is considered that the hypoxia may be localized and limited to a single organ or organ system, it becomes apparent that the two conditions are not mutually exclusive

Another important aspect of respiratory metabolism in congestive failure is the exchange of carbon dioxide In the average patient in failure, changes in carbon dioxide exchange may be minimal. If, however, pulmonary function is compromised by pneumonia, pulmonary infarction, or massive pleural effusion, the removal of carbon dioxide may be interfered with If the resultant retention of carbon dioxide is of sufficient mag-

nitude, serum carbonic acid and serum bicarbonate concentrations rise resulting in *respiratory acidosis* (Fig 18-3A) The narcosis of the medullary respiratory centers accompanying respiratory acidosis and the dangers attendant on oxygen administration under such circumstances are well known and need no further comment.

Water Metabolism. One of the prominent clinical findings in patients with congestive heart failure is the presence of *dependent edema, ascites,* and often *pleural effusion* These findings are directly related to alterations in water metabolism Numerous studies of water metabolism in these patients have been reported; however, the precise mechanism by which water metabolism is altered in this disease state is still unknown The early studies of Starling suggested that edema fluid was retained through a mechanism of transudation and that this was due to increased capillary pressure resulting from backward *failure.* Studies performed in carefully controlled clinical situations have demonstrated that this explanation is not tenable in every instance As a result, other explanations have been sought. Studies of urine extracts have demonstrated that *the urine of patients with congestive heart failure contains an increased quantity of an antidiuretic substance somewhat similar to that found in extracts of the posterior pituitary gland* (Bercu et al.). Other studies have presented evidence that, in heart failure, the increased amounts of antidiuretic substance do not result from decreased destruction of this material but rather from increased production (White et al). This finding would suggest that in part the altered water metabolism of congestive heart failure is related to an increased formation of posterior pituitary antidiuretic substance The stimulus to the production of an increased quantity of antidiuretic substance, however, has not been accurately identified. In the classic work of Verney, it was demonstrated that an increase in the osmolarity of the blood entering the area of the pituitary stalk, the posterior pituitary, and the supraoptical hypophyseal nuclei would produce an antidiuretic response and, therefore, presumably an increased secretion of antidiuretic hormone. It has been proposed that, early in the course of congestive failure, there is a phase of increased intravascular osmolarity resulting from a decreased intravascular volume This would provide the necessary stimulus for an increased secretion of

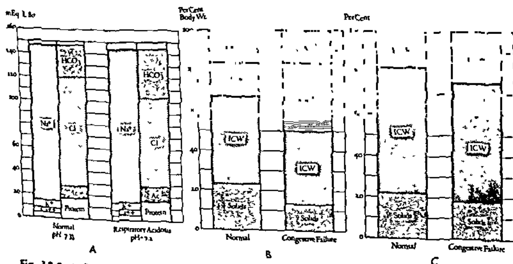

Fig. 18-3 A Respiratory acidosis Note that the principal changes in serum electrolytes consist of an increase in carbonic acid and in bicarbonate with a decrease in serum chloride and in pH. B. Changes in body composition in congestive *failure Left* average percentage composition of a normal individual in health. Right average percentage *body composition* in congestive heart failure with *edema* C The percentage composition of solids, extracellular water (ECW) and intracellular water (ICW) in fresh, fat-free muscle samples obtained from normal persons and patients with edema due to congestive heart failure *Note that* the changes in these components parallel the changes in total body composition (B).

posterior pituitary antidiuretic hormone. The ultimate significance of the presence of such antidiuretic substances in the urine of patients with failure, together with the possible relationship of this fact to the pathogenesis of heart failure, remains to be elucidated.

In the recent studies of Laragh et al., edema was produced in dogs despite the fact that the animals had been rendered free of functioning posterior pituitary tissue. This would suggest that some factors, in addition to the posterior pituitary antidiuretic hormone, play a role in the retention of water in congestive heart failure or that antidiuretic hormone can be elaborated by other areas of the brain.

In addition to an increased quantity of antidiuretic hormone, several workers have demonstrated increased amounts of *adrenocortical substances in the urine* of patients with congestive heart failure (Deming et al.; Singer et al.). It has been proposed that the decreased volume of intravascular fluid associated with the hyperosmolarity previously mentioned provides a stimulus to the formation of increased adrenocortical hormones In addition, the stress of acute congestive failure undoubtedly contributes an additional stimulus to this mechanism. Whether the presence of increased adrenal hormones in the urine of patients in congestive heart failure represents a prime cause of the symptoms of congestive heart failure or whether it reflects still another concomitant manifestation of congestive heart failure is unknown. Certainly, these substances play a role in the altered electrolyte metabolism that is seen in heart failure, and, therefore, are undoubtedly secondarily related to the altered water metabolism.

Another mechanism which may contribute to the edema of congestive heart failure is *glomerulotubular imbalance*, as proposed by Mokotoff et al. According to this mechanism, glomerular filtration is decreased in heart failure while tubular reabsorptive capacity remains intact. As a result, water and sodium are retained. Such an explanation becomes untenable when it is observed that patients with heart failure may become edema-free despite the fact that the glomerular filtration rate remains at a low level. If, on the other hand, the decreased glomerular filtration rate is regarded as an incidental finding in heart failure and one postulates *an increased tubular reabsorptive capacity for sodium and water*, then by definition *glomerulotubular imbalance* may play an important role in the accumulation of edema fluid in heart failure. Unfortunately, the critical measurements of these discrete renal functions cannot be adequately performed with currently available techniques. The alterations in the discrete renal functions of sodium and water excretion described by Newman may play a significant role in the altered water metabolism of heart failure.

Numerous investigators have studied the total quantity of body water in patients in congestive heart failure while others have studied individual tissues for their water content. Studies of total body water have been carried out with the use of various dilution techniques, utilizing tritium- or deuterium-labeled water, antipyrine, or one of the antipyrine derivatives. Although some controversy persists with regard to the accuracy with which these substances measure the total body water individually, most investigators have agreed that *in congestive heart failure the estimated total body water is increased*. However, this increase is often not proportional to the amount of peripheral edema that is observed clinically. This discrepancy between the degree of clinically estimated edema and the measured quantity of water requires an additional explanation

It has been suggested that the relatively small increase in total body water as measured by these various techniques compared with the marked amount of edema sometimes observed clinically, results from *a marked increase in extracellular water* accompanied by a loss of intracellular water. Such an explanation requires an alteration in water distribution associated with a loss of tissue solids (Fig. 18-3B) Direct determinations on specimens of skeletal muscle obtained from edematous areas in patients with congestive heart failure lend credence to this explanation (Fig. 18-3C). The relationship of water metabolism to changes in tissue solids will be discussed further under protein metabolism With appropriate therapy, the total water content of patients with congestive failure promptly returns to normal.

Sodium Chloride. The recognition of the possible relationship of *sodium* and *chloride* to the manifestations of heart failure dates

back to antiquity Only in more recent times, however, have the independent mechanisms by which these ions are metabolized been recognized. In the average American diet, the intake of sodium averages from 100 to 175 milliequivalents daily Over the world as a whole, this value varies over a much wider range, depending upon the availability of salt, eating habits, and culture. Under normal circumstances, this amount of sodium is excreted each day via the skin, in the feces, and in the urine. In the presence of congestive heart failure the capacity of each of these avenues of sodium excretion becomes markedly diminished, most important, however, appears to be *the inability of the kidney to excrete sodium* In some patients with congestive failure, the amount of sodium recovered from the urine in a 24-hr period may approach zero, *even in the* presence of a considerable intake *of this ion* In this regard, studies on patients who have heart disease without edema have revealed that an increase in exchangeable sodium and in extracellular fluid volume occurs in these patients before a decrease in the ability of the kidney to excrete sodium is detectable (Hollander and Chobanian) The ultimate *mechanism* or mechanisms by which renal *sodium retention develops is unknown.* The possible role of *adrenocortical steroids in* the genesis of *edema in heart failure* has already been mentioned in the section on water metabolism. The *influence* of the adrenal steroids on renal tubular sodium reabsorption is well known

More recently, *interest* has been focused on *aldosterone* as the cause *of sodium retention* in this situation Bioassay studies of urine from patients with congestive heart failure have demonstrated that tremendous *quantities of this* substance may be present (Luetscher and Johnson). Such observations suggest that increased aldosterone production *may play a* role in the retention of sodium It is of interest that patients with *primary hyperaldosteronism do not* manifest peripheral edema, but present all *of the* other manifestations of increased aldosterone levels which are absent in congestive failure This problem has been reviewed by Johnson and Conn.

Measurements of exchangeable sodium[1] on patients with edema due to congestive heart failure have been carried out by several investigators These studies have demonstrated that the content of *exchangeable sodium* is significantly *increased* in all patients with congestive heart failure. Further, the increase in exchangeable sodium is disproportionately greater than is the increase in total body water. This can be explained in part by a marked increase in extracellular water, which has a high concentration of sodium, accompanied by a decrease in intracellular water, which is low in sodium or sodium-free (Fig. 18-3B). However, *the increase in exchangeable sodium* is large enough to suggest that other sodium stores are probably involved as well. Such potential stores include connective tissue, cartilage, and bone. It is of interest that the increase in the value for exchangeable *sodium* is often increased prior to the appearance of clinical edema and frequently remains elevated *for long intervals* after clinical edema has disappeared.

One other aspect of *sodium metabolism* in congestive heart failure which deserves consideration is the problem of *hyponatremia* In general, a serum sodium concentration of 135 *mEq/liter* is regarded as representing the lower limit of normal. Serum sodium concentrations lower than this are occasionally *observed in patients with* heart failure (Fig 18-4A). This finding usually *reflects a redistribution of sodium* in the presence of a total body excess of the ion and does not represent a deficiency syndrome.

The *chloride ion*, like the sodium ion, is predominantly extracellular, although it does occur *intracellularly* in certain tissues, such as the red blood cells, the gastric mucosa, and the testicle. In congestive failure, the body chloride increases in proportion to the extracellular fluid. Of greater importance, however, is the role that the chloride ion plays in the acid-base *metabolism* in congestive heart *failure In* uncomplicated and untreated congestive *failure*, the serum chloride concentration *remains* normal *despite* an increase in the total body chloride content *Following* the ad-

[1] Exchangeable sodium represents that portion of the body's total sodium stores which reaches equilibrium rapidly *following* injection of radioactive sodium Studies *indicate* that approximately two-thirds of the body's total *sodium* is exchangeable

posterior pituitary antidiuretic hormone. The ultimate significance of the presence of such antidiuretic substances in the urine of patients with failure, together with the possible relationship of this fact to the pathogenesis of heart failure, remains to be elucidated.

In the recent studies of Laragh et al., edema was produced in dogs despite the fact that the animals had been rendered free of functioning posterior pituitary tissue This would suggest that some factors, in addition to the posterior pituitary antidiuretic hormone, play a role in the retention of water in congestive heart failure or that antidiuretic hormone can be elaborated by other areas of the brain.

In addition to an increased quantity of antidiuretic hormone, several workers have demonstrated increased amounts of *adrenocortical substances* in the urine of patients with congestive heart failure (Deming et al.; Singer et al.). It has been proposed that the decreased volume of intravascular fluid associated with the hyperosmolarity previously mentioned provides a stimulus to the formation of increased adrenocortical hormones. In addition, the stress of acute congestive failure undoubtedly contributes an additional stimulus to this mechanism. Whether the presence of increased adrenal hormones in the urine of patients in congestive heart failure represents a prime cause of the symptoms of congestive heart failure or whether it reflects still another concomitant manifestation of congestive heart failure is unknown. Certainly, these substances play a role in the altered electrolyte metabolism that is seen in heart failure, and, therefore, are undoubtedly secondarily related to the altered water metabolism

Another mechanism which may contribute to the edema of congestive heart failure is *glomerulotubular imbalance*, as proposed by Mokotoff et al. According to this mechanism, glomerular filtration is decreased in heart failure while tubular reabsorptive capacity remains intact. As a result, water and sodium are retained. Such an explanation becomes untenable when it is observed that patients with heart failure may become edema-free despite the fact that the glomerular filtration rate remains at a low level If, on the other hand, the decreased glomerular filtration rate is regarded as an incidental finding in heart failure and one postulates *an increased tubular reabsorptive capacity for sodium and water*, then by definition glomerulotubular imbalance may play an important role in the accumulation of edema fluid in heart failure Unfortunately, the critical measurements of these discrete renal functions cannot be adequately performed with currently available techniques. The alterations in the discrete renal functions of sodium and water excretion described by Newman may play a significant role in the altered water metabolism of heart failure.

Numerous investigators have studied the total quantity of body water in patients in congestive heart failure while others have studied individual tissues for their water content. Studies of total body water have been carried out with the use of various dilution techniques, utilizing tritium- or deuterium-labeled water, antipyrine, or one of the antipyrine derivatives. Although some controversy persists with regard to the accuracy with which these substances measure the total body water individually, most investigators have agreed that *in congestive heart failure the estimated total body water is increased*. However, this increase is often not proportional to the amount of peripheral edema that is observed clinically. This discrepancy between the degree of clinically estimated edema and the measured quantity of water requires an additional explanation.

It has been suggested that the relatively small increase in total body water as measured by these various techniques compared with the marked amount of edema sometimes observed clinically, results from *a marked increase in extracellular water* accompanied by a loss of intracellular water. Such an explanation requires an alteration in water distribution associated with a loss of tissue solids (Fig. 18-3B). Direct determinations on specimens of skeletal muscle obtained from edematous areas in patients with congestive heart failure lend credence to this explanation (Fig. 18-3C). The relationship of water metabolism to changes in tissue solids will be discussed further under protein metabolism With appropriate therapy, the total water content of patients with congestive failure promptly returns to normal.

Sodium Chloride. The recognition of the possible relationship of *sodium* and *chloride* to the manifestations of heart failure dates

ing from congestive failure have demonstrated a cumulative balance of potassium which may be positive, negative, or zero Similarly, serial studies of exchangeable potassium in patients recovering from heart failure have demonstrated that, in some instances, the value for exchangeable potassium may increase whereas in others this value may diminish. It is of interest that patients in whom the value for exchangeable potassium decreased progressively despite therapy succumbed to congestive failure, patients in whom the value for exchangeable potassium increased, recovered These observations are of significance when interpreted in relationship to the alterations in protein metabolism Several investigators have demonstrated that during recovery from congestive heart failure a significant amount of nitrogen is retained. This positive nitrogen balance reflects a restoration of tissue protein stores In addition, it is of interest that, in samples of skeletal muscle obtained in patients during and following recovery from congestive failure, the ratio of potassium to nitrogen remains remarkably constant. This would suggest that, in patients with congestive heart failure who fail to achieve a positive potassium balance, there is a concomitant failure to achieve a positive nitrogen balance

In seeking an explanation for these alterations …

…sultant inadequate dietary intake may be a contributing factor. The increased metabolic rate previously referred to, increases the rate of tissue breakdown and increases the requirement for nutrient materials Superimposed infections, such as pneumonia or genitourinary infections, further increase the requirements and contribute to the negative nitrogen balance Congestive changes in the liver may interfere with liver function and limit the rate of synthesis of protein materials In addition, patients with congestive failure are forced to lead inactive sedentary lives and, as a result, skeletal muscle atrophies and is replaced by fat Finally, the stress of congestive failure with its concomitant discharge of adrenocortical substances provides an additional set of factors which contribute to tissue breakdown during the course of congestive heart failure.

The significance of a loss of body tissue in congestive heart failure has already been alluded to in the section on water metabolism. Recent studies of body composition in cachectic patients with congestive heart failure have demonstrated that, in these patients, there is loss of muscular tissue out of proportion to the loss of body fat (Fig. 18-3B). This situation is similar to the changes in body composition seen in patients with "wasting diseases" It would appear that, in congestive failure, the changes in body composition are similar to those associated with placing a fat man in a lean man's body In other words, cardiac cachexia is characterized by a marked loss of lean tissue, and an increase in relative body water and body fat content.

Fat. Many patients with congestive failure are obese This is particularly true in the middle-aged and elderly patient population The role of obesity in contributing to the pathogenesis of congestive failure is widely recognized in that excess fat increases the work demands upon the heart Unfortunately, accurate measurements of body fat content have not been carried out in patients with heart failure and the changes in body fat stores which may result from chronic heart failure or recurrent heart failure are inadequately understood despite the fact that the marked cachexia of chronic heart disease has long been recognized Most currently available methods for estimating body fat assume a normal body water content and, therefore, cannot be utilized in edematous patients. Other methods utilizing measurements of skin-fold thickness or x-ray diffraction techniques have not been standardized in edematous patients and are not applicable. Newer techniques for estimating body fat in the presence of congestive failure are currently being developed and, as they are applied, medical knowledge of the changes in body fat and lean-body mass will provide a more adequate description of the changes in body composition seen in congestive heart failure.

In summary, the metabolic aspects of congestive heart failure include alterations in the metabolism of water, sodium, chloride, potassium, and nitrogen. Total body water may be increased only slightly over the normal but, because of altered relationships between intracellular and extracellular phases, even small

ministration of *ammonium chloride* as a diuretic, the serum chloride concentration will rise in varying degrees depending upon the size of the dose, the amount of absorption, and the ability of the kidney to handle the increased chloride load. The increase in serum chloride concentration leads to a *hyperchloremic acidosis* of varying degrees of severity (Fig. 18-4B). If the hyperchloremia is moderate in degree, it has a transient diuretic effect in that, for 24 to 36 hr following the institution of therapy with ammonium chloride, a diuresis of water and sodium generally occurs. After 36 hours of continuous therapy, the ammonium-producing mechanism of the renal tubules comes into play and the diuresis of water and sodium is discontinued. In patients with extensive renal damage, the ability of the renal tubules to produce ammonium ion may be sufficiently diminished so that the excess load of chloride ion continues to be excreted in association with sodium ions. Under these circumstances, the chloride acidosis may become progressively more severe and can occasionally lead to death. In some patients with severe congestive failure, the sodium-retaining mechanism of the renal tubules may be so marked that the administration of ammonium chloride may not produce a sodium diuresis but instead may result in a significant renal loss of potassium. Generally, however, this is not manifested by a decreased serum potassium concentration. In acidosis, *hyperkalemia*, rather than hypokalemia, is the rule.

Another aspect of chloride metabolism associated with the therapy of congestive failure is the *hypochloremic alkalosis* which may follow the administration of *mercurial diuretics* (Fig. 18-4C). Since the organic mercurial compounds tend to promote a chloruresis out of proportion to the accompanying diuresis of sodium, the serum chloride concentration falls and this is accompanied by an increase in serum bicarbonate concentration and in serum pH. Frequently, the serum potassium concentration is also decreased under these circumstances and this hypokalemia may be manifested by muscular weakness and symptoms of digitalis intoxication. As a rule, when the serum chloride concentration falls to 85 mEq/liter or less, further administration of mercurials fails to produce a water diuresis, but the loss of chloride continues and the progressively more severe hypochloremic alkalosis may lead to coma and occasionally death.

Potassium and Nitrogen Metabolism. The importance of the potassium ion in relationship to cardiac function has been recognized for many years. However, the total metabolism of potassium by the patient in congestive heart failure was not investigated until much later. Metabolic balance studies in patients recover-

ing from congestive failure have demonstrated a cumulative balance of potassium which may be positive, negative, or zero. Similarly, serial studies of exchangeable potassium in patients recovering from heart failure have demonstrated that, in some instances, the value for exchangeable potassium may increase whereas in others this value may diminish It is of interest that patients in whom the value for exchangeable potassium decreased progressively despite therapy succumbed to congestive failure, patients in whom the value for exchangeable potassium increased, recovered. These observations are of significance when interpreted in relationship to the alterations in protein metabolism Several investigators have demonstrated that during recovery from congestive heart failure a significant amount of nitrogen is retained. This positive nitrogen balance reflects a restoration of tissue protein stores In addition, it is of interest that, in samples of skeletal muscle obtained in patients during and following recovery from congestive failure, the ratio of potassium to nitrogen remains remarkably constant. This would suggest that, in patients with congestive heart failure who fail to achieve a positive potassium balance, there is a concomitant failure to achieve a positive nitrogen balance.

In seeking an explanation for these altera-tions

resultant inadequate dietary intake may be a contributing factor The increased metabolic rate previously referred to, increases the rate of tissue breakdown and increases the requirement for nutrient materials Superimposed infections, such as pneumonia or genitourinary infections, further increase the requirements and contribute to the negative nitrogen balance. Congestive changes in the liver may interfere with liver function and limit the rate of synthesis of protein materials. In addition, patients with congestive failure are forced to lead inactive sedentary lives and, as a result, skeletal muscle atrophies and is replaced by fat. Finally, the stress of congestive failure with its concomitant discharge of adrenocortical substances provides an additional set of factors which contribute to tissue breakdown during the course of congestive heart failure.

The significance of a loss of body tissue in congestive heart failure has already been alluded to in the section on water metabolism. Recent studies of body composition in cachectic patients with congestive heart failure have demonstrated that, in these patients, there is loss of muscular tissue out of proportion to the loss of body fat (Fig. 18-3B). This situation is similar to the changes in body composition seen in patients with "wasting diseases" It would appear that, in congestive failure, the changes in body composition are similar to those associated with placing a fat man in a lean man's body. In other words, cardiac cachexia is characterized by a marked loss of lean tissue, and an increase in relative body water and body fat content.

Fat. Many patients with congestive failure are obese. This is particularly true in the middle-aged and elderly patient population. The role of *obesity* in contributing to the pathogenesis of congestive failure is widely recognized in that excess fat increases the work demands upon the heart Unfortunately, accurate measurements of body fat content have not been carried out in patients with heart failure and the changes in body fat stores which may result from chronic heart failure or recurrent heart failure are inadequately understood despite the fact that the marked cachexia of chronic heart disease has long been recognized Most currently available methods for estimating body fat assume a normal body water content and, therefore, cannot be utilized in edematous patients. Other methods utilizing measurements of skin-fold thickness or x-ray diffraction techniques have not been standardized in edematous patients and are not applicable. Newer techniques for estimating body fat in the presence of congestive failure are currently being developed and, as they are applied, medical knowledge of the changes in body fat and lean-body mass will provide a more adequate description of the changes in body composition seen in congestive heart failure.

In summary, the metabolic aspects of congestive heart failure include alterations in the metabolism of water, sodium, chloride, potassium, and nitrogen. Total body water may be increased only slightly over the normal but, because of altered relationships between intracellular and extracellular phases, even small

ministration of *ammonium chloride* as a diuretic, the serum chloride concentration will rise in varying degrees depending upon the size of the dose, the amount of absorption, and the ability of the kidney to handle the increased chloride load. The *increase in serum* chloride concentration leads to a *hyperchloremic acidosis* of varying degrees of severity (Fig. 18-4B). If the hyperchloremia is moderate in degree, it has a transient diuretic effect in that, for 24 to 36 hr following the institution of therapy with ammonium chloride, a diuresis of water and sodium generally occurs. After 36 hours of continuous therapy, the ammonium-producing mechanism of the renal tubules comes into play and the diuresis of water and sodium is discontinued In patients with extensive renal damage, the ability of the renal tubules to produce ammonium ion may be sufficiently diminished so that the excess load of chloride ion continues to be excreted in association with sodium ions Under these circumstances, the chloride acidosis may become progressively more severe and can occasionally lead to death In some patients with severe congestive failure, the sodium-retaining mechanism of the renal tubules may be so marked that the administration of ammonium chloride may not produce a sodium diuresis but instead may result in a significant renal loss of potassium Generally, however, this is not manifested by a decreased serum potassium concentration. Extracardiac factors of heart failure

PETER TALSO

Heart disease by its very definition presupposes an abnormal condition involving the structures of the heart *as an organ*. *In many* instances the heart itself may be structurally and functionally normal but, because of the operation of factors outside of the heart, symptoms and manifestations of heart disease become evident. In general, such extracardiac factors interfere with the integrity of the circulation by placing increased demands upon the heart. In other instances, however, a systemic disease process may influence the heart incidentally and occasionally the cardiac manifestations may be most prominent.

In the present discussion, extracardiac factors will be considered in the following categories:

1. Infections
2. Anemias
3. Endocrine factors
   - *a* Hyperthyroidism
   - *b* Hypothyroidism
   - *c* Adrenal factors
   - *d* Pituitary factors
4. Nutritional factors
   - *a* Beriberi
   - b Cirrhosis
   - c Obesity
5. Pregnancy
6. Paget's disease of bone
7. Muscular dystrophies

This list is not intended to be exhaustive, but serves to *emphasize* the wide variety of factors which may be operative in producing manifestations of cardiac disease in a given patient. Their importance lies in the fact that many of them can be corrected and thus the prospects for recovery are vastly improved.

INFECTIONS

The relationship of specific infectious processes, such as rheumatic fever, syphilis, and certain viral diseases, to diseases of the heart are well known and have been adequately documented in other sections of this text (see Part 8). In addition to these, however, infections generally may have an effect upon the heart. It is well known that, as the body temperature rises, the rate of metabolism increases approximately 13 per cent for each degree of fever above normal on the centigrade scale. With this, cardiac output increases proportionately through increases of heart rate and stroke volume. In individuals with normal hearts, this increase in cardiac work is readily tolerated and symptoms referable to the heart are minimal. If, however, the heart's integrity has already been compromised by the presence of such conditions as mitral stenosis, hypertension, or atherosclerotic heart disease, then *the increased demands occasioned by the fever may precipitate congestive heart failure*. It is important for the clinician to realize that minor infections, which are of no consequence to normal persons, may be of sufficient importance in persons with heart disease to initiate serious and even fatal congestive heart failure. In elderly persons, infections and the accompanying fever may result in *atrial fibrillation*, which in turn can lead to congestive failure. As a result, every patient undergoing an episode of congestive heart failure should be studied carefully in order to eliminate the possibility of a secondary infection as the precipitating cause.

increments of water may produce spectacular clinical edema. Body sodium stores are increased, and this increase is much greater proportionately than is the increase in body water. Body chloride is increased in proportion to the increase in extracellular water. Changes in serum chloride concentration may be induced by conventional therapeutic procedures and may occasionally play a major role in determining the outcome of an individual case Body potassium and nitrogen stores are depleted and this loss of tissue appears to influence the distribution of water. The capacity of the patient to replenish these tissue stores may determine to a significant degree the patient's recovery.

defects, e g., rheumatic, atherosclerotic, or *hypertensive conditions*, are present as underlying causative factors.

Therapy of thyrotoxicosis has been greatly simplified by the availability of I^{131}, although in patients of childbearing age, antithyroid drugs such as propylthiouracil and methylthiouracil, used together with surgery, are still advocated

MYXEDEMA

Therapeutically induced hypothyroidism has been recommended in the management of selected cases of congestive heart failure and coronary heart disease In many instances, the results of such therapy have been gratifying, yet spontaneous myxedema may result in cardiac enlargement, pericardial effusion, and even congestive heart failure The relationship of myxedema to elevated serum cholesterol levels and to the development of atherosclerosis is well known, and patients with severe hypothyroidism may experience precordial pain

The classical patient with myxedema is easily recognized because of his placid, sleepy appearance, poor memory, sensitivity to cold, dry, coarse skin, thick lips and tongue; and scant hair with thinning of the eyebrows In contrast, some patients may appear outwardly nervous and distraught, and their behavior may seem manic The diagnosis can usually be established by determining the basal metabolic rate, although this determination may be misleading since the value for "basal" oxygen consumption tends to rise with the onset of congestive heart failure The circulation time is usually prolonged and the serum cholesterol level is markedly elevated in myxedema Anemia is frequently present and has occasionally been confused with pernicious anemia Characteristically, the anemia is normocytic and normochromic, and responds only to thyroid extract

The electrocardiogram exhibits changes which may provide the clue that leads to the diagnosis Characteristically, it exhibits bradycardia, low voltage of atrial and ventricular complexes, and T waves which are flat or inverted The diagnosis can be established by means of I^{131} uptake studies, protein-bound iodine determinations, and hormonal I^{131} conversion ratios The factors which may interfere with these determinations have been discussed in relationship to thyrotoxicosis. Finally, if doubt in the diagnosis persists, a therapeutic test with small doses of thyroid extract may be utilized.

Therapy of myxedema may be achieved with thyroid extract, sodium L-thyroxine, or triiodothyronine. Because of the danger of precipitating attacks of precordial pain, initial dosage should be small and should not exceed ¼ grain of thyroid extract or its equivalent daily Maintenance dosage must be carefully adjusted and should be tailored to the needs of the individual Often, the result obtained may be somewhat less than optimal as far as the myxedema is concerned, however, this is preferable to pushing the dose of thyroid to the point at which the patient's pain becomes a threat to his existence.

PITUITARY AND ADRENAL FACTORS

In the section dealing with the metabolic aspects of congestive heart failure, the roles of the posterior pituitary antidiuretic hormone and of aldosterone in the genesis of congestive heart failure have already been discussed (Chap 3) They are listed at this point merely to include them among the extracardiac factors which play a role in heart disease. In all probability, these factors play such an important role in the development of these manifestations that they should be regarded as a part of the series of physiological responses which occur in the organism during failure of the heart.

NUTRITIONAL DISORDERS

Among the nutritional disorders which may produce cardiac manifestations, beriberi is perhaps the most widely recognized (*see* Part 16, Chap 11) A deficiency of thiamine interferes with glucose metabolism and pyruvate accumulates in the blood and tissues This block in carbohydrate metabolism in the citric acid cycle interferes with energy production by the myocardium and is responsible in part for the production of the manifestations of beriberi heart disease In the usual case, there is a high cardiac output and an increased stroke volume, together with peripheral vasodilatation, a bounding pulse, increased pulse pressure, diminished circulation time, and a decreased arteriovenous oxygen difference Although beriberi heart disease has come to be

ANEMIA

Anemia, which is severe and chronic, may produce cardiac manifestations through several mechanisms (see Part 16, Chap. 11). Cardiac output *is increased to compensate for* the reduced oxygen-carrying capacity of the blood. This can result in cardiac hypertrophy and ultimately in congestive heart failure. If coronary flow fails to increase sufficiently to compensate for the decrease in hemoglobin concentration, the patient may experience attacks of precordial pain. Finally, chronic anemia with its resultant myocardial hypoxia may lead to degenerative changes involving the heart muscle, these may lead to a further decrease *in the reserve of the heart*

The characteristic symptoms of severe anemia include dyspnea, easy fatigability, and palpitation. Precordial pain may occur even in young patients and in the absence of significant coronary atherosclerosis. Peripheral edema may occur but is usually a manifestation of a nutritional deficiency associated with the anemia. Physical examination reveals general pallor, a rapid bounding pulse with a widened pulse pressure, and "hemic" mur*murs, which may be systolic or diastolic in* time. Although the usual *hyperkinetic circulatory syndrome* associated with anemia is widely known and easily recognized, a significant number of patients with anemia may manifest an entirely different adjustment to the decreased oxygen-carrying capacity of the blood. In this group, the heart rate is normal or slow, the velocity of peripheral blood flow is reduced, and cardiac output is normal or low. The precise mechanism by which this alternate mechanism of compensation for chronic anemia develops is unknown.

In the management of patients with cardiovascular disease, the presence of a coexistent anemia *should always be kept in mind and* every effort should be made to establish its cause and to correct it. In treating the anemia itself, it should be recognized that, although transfusions of whole blood may provide the most direct means of correcting the anemia, this procedure may precipitate congestive failure As a result, if blood is to be administered to any severely anemic patient, it should be given slowly, in small volumes, and under constant supervision.

ENDOCRINE FACTORS

Of the various endocrine factors which may influence the state of the circulation. *hyperthyroidism* is probably the commonest *(see Part 16, Chap 10). It should* be suspected in every patient with congestive failure and atrial fibrillation when the ventricular rate fails to respond to adequate digitalization The presence of wide staring eyes, a fine tremor of the fingers, silky smooth skin, weight loss, increased frequency of bowel movements, or a salmon-colored facies, should provide a clue suggesting hyperthyroidism In many instances, however, the presence of an overly active thyroid may be masked, *and a normal sinus rhythm with* a normal heart rate does not necessarily rule out the presence of thyrotoxicosis. The diagnosis of hyperthyroidism may present some difficulty. As suggested above, the symptoms and signs may influence the clinician in the wrong direction The measurement of the basal metabolic rate is often unreliable because of the effect of congestive failure on this determination. The estimation of the thyroid uptake of I^{131} can be helpful but at times may *be misleading. Falsely high values* may occur as a result of iodine deficiency following prolonged dietary salt restriction *Low values* may be obtained when patients have unknowingly received preparations such as *iodides*, sulfonamides, certain mercurial diuretics, or radiographic contrast media When doubt exists, additional laboratory studies should include determinations of the serum cholesterol, the protein-bound iodine, and the I^{131} conversion ratio. Finally, the response of the I^{131} uptake to the administration of thyroid hormone or triiodothyronine may be determined In normal subjects, the uptake of I^{131} is decreased following therapy with thyroid hormone while *in thyrotoxic subjects this* response does not occur

In the presence of excess circulating thyroid hormone, the oxygen needs of all tissues including the myocardium are increased. This increased demand is met by an increase in cardiac output largely effected through an increase in heart rate. It has been *estimated that* some 20 per cent of patients with thyrotoxic heart disease have no underlying cardiac abnormality. In the remainder, cardiovascular

cent above the normal during the thirty-second week. These physiologic adjustments of pregnancy must be kept in mind in patients with organic heart disease who anticipate a pregnancy and in pregnant patients who develop signs and symptoms of congestive heart failure.

PAGET'S DISEASE OF BONE

In Paget's disease of bone, functional arteriovenous fistulas develop in the involved bones resulting in increased regional blood flows. In some cases, significant increases in cardiac output have been reported, and it has been suggested that congestive failure might occur on this basis alone. However, Paget's disease occurs more commonly in patients in the later decades of life, and it is probable that the onset of congestive failure represents the combined effects of a primary cardiac defect and the peripheral arteriovenous fistulas of Paget's disease. Additional functional studies in patients with Paget's disease will be required in order to clarify and quantitate the mechanisms by which this condition influences cardiovascular function.

MUSCULAR DYSTROPHIES

Most descriptions of the muscular dystrophies have been limited to those of the clinical involvement of the skeletal musculature (see Part 16, Chap. 9). However, pathological studies have demonstrated that the myocardium is involved in more than one-half of all autopsied cases, and death has been attributed to congestive failure in more than one-third of all cases. A variety of electrocardiographic changes has been reported during life in such patients, and consist predominantly of tachycardia, short P-R intervals, broad QRS complexes, deep Q waves, and abnormal P waves. Manifestations of congestive heart failure are rarely seen presumably because of the enforced inactivity; however, heart failure may occur suddenly and may be a terminal event in the disease process. Since the pathological changes found in the hearts of such patients are identical with those found in skeletal muscle, every patient with progressive muscular dystrophy should be regarded as a potential cardiac patient and should therefore be treated accordingly.

SUMMARY

A number of factors operating primarily outside of the realm of the heart and the great vessels may indirectly influence the work of the heart or may coincidentally involve the heart and so produce symptoms and signs of heart disease. As a result, it behooves the clinician to be aware of these various factors and to approach the management of every patient with cardiovascular disease with all of these extracardiac factors in mind.

relatively rare in the United States as a result of the general high standard of living and the widespread use of vitamin supplements in various food items, such as white bread, the disease still occurs and the possibility of thiamine deficiency in any patient with congestive heart failure should be kept in mind. The criteria for beriberi heart disease set up by Blankenhorn (1946) continue to be applicable: (1) unclear pathogenesis, (2) history of 3 or more months on a thiamine-deficient diet; (3) signs of peripheral neuritis or pellagra, (4) cardiomegaly with sinus rhythm; (5) edema, high venous pressure, anemia, and hypoproteinemia; (6) minimal electrocardiographic changes; and (7) recovery with decrease in heart size following specific therapy.

An unusual variation of beriberi heart disease, in which acute arterial hypertension developed and congestive heart failure followed, has been described by Walters. It is likely that many atypical cases go unrecognized and, because of inadequate therapy, they may progress to a severe and irreversible stage.

In *cirrhosis of the liver*, the presence of ankle edema, ascites, collateral portal circulation, and vascular spiders, together with a history of an inadequate diet and alcoholism, usually suffice to make the diagnosis Occasionally, however, manifestations of congestive failure are superimposed upon cirrhosis, and these may go undetected. The heart may be involved in the presence of cirrhosis because of intrinsic myocardial disease or it may be influenced because of malnutrition and its allied metabolic defects, the effects of arteriovenous shunts (together with the accompanying increase in blood volume), and the effects of distorted water and electrolyte exchange, perhaps prompted by failure of the diseased liver to inactivate the hormones which normally regulate these moieties Striking enlargement of the heart and obvious congestive failure, however, are uncommon in patients who have cirrhosis in the absence of underlying heart disease.

The adverse effects of *obesity* in reference to cardiovascular morbidity and mortality are well known and constitute an important factor in the establishment of life-insurance actuarial tables In recent years, *a reversible cardiopulmonary syndrome associated with extreme obesity* has been described by several authors. This syndrome includes somnolence, cyanosis, polycythemia, periodic breathing, right axis deviation of the electrocardiogram, and congestive heart failure. In most instances, patients with this syndrome have weighed over 300 pounds and all symptoms and signs have disappeared following the loss of appropriate amounts of weight.

The exact mechanism by which obesity causes the signs and symptoms of this syndrome are unknown. The limited number of studies which have been performed suggest that pulmonary hypoventilation is produced by the mechanical disadvantage of the obesity and that this, associated with periodic breathing, leads to hypercapnia and hypoxia. These in turn result in polycythemia, pulmonary hypertension, right ventricular hypertrophy, and congestive failure Although the mechanisms involved are at present unclear, the clinician should recognize the occurrence of this syndrome and should orient the therapy of the obese patient with these factors in mind.

PREGNANCY

Aterations in cardiovascular dynamics which occur during pregnancy may be interpreted as representing a normal physiologic response to the pregnant state In the patient with a normal heart, these adjustments produce no ill effects, however, in subjects with underlying heart disease, the physiologic alterations of pregnancy may result in severe and sometimes fatal congestive heart failure. The circulatory effects of pregnancy may be noted in the second month of gestation and progress gradually to reach a maximum during the thirty-second week. Thereafter, the intensity of these manifestations declines until the time of delivery Clinically, the effects of pregnancy are manifested by an increased heart rate, palmar flushing, a bounding pulse, capillary pulsations, a prominent apical impulse, and systolic murmurs located at both the apex and base of the heart. Functional studies performed during pregnancy have demonstrated that oxygen consumption increases by 15 to 20 per cent, cardiac output may increase by as much as 50 per cent, the venous pressure rises, and the retention of sodium and water may result in hemodilution amounting to an increase of plasma volume as much as 45 per

cent above the normal during the thirty-second week These physiologic adjustments of pregnancy must be kept in mind in patients with organic heart disease who anticipate a pregnancy and in pregnant patients who develop signs and symptoms of congestive heart failure

PAGET'S DISEASE OF BONE

In Paget's disease of bone, functional arteriovenous fistulas develop in the involved bones resulting in increased regional blood flows In some cases, significant increases in cardiac output have been reported, and it has been suggested that congestive failure might occur on this basis alone However, Paget's disease occurs more commonly in patients in the later decades of life, and it is probable that the onset of congestive failure represents the combined effects of a primary cardiac defect and the peripheral arteriovenous fistulas of Paget's disease Additional functional studies in patients with Paget's disease will be required in order to clarify and quantitate the mechanisms by which this condition influences cardiovascular function

MUSCULAR DYSTROPHIES

Most descriptions of the muscular dystrophies have been limited to those of the clinical involvement of the skeletal musculature (see Part 16, Chap 9). However, pathological studies have demonstrated that the myocardium is involved in more than one-half of all autopsied cases, and death has been attributed to congestive failure in more than one-third of all cases. A variety of electrocardiographic changes has been reported during life in such patients, and consist predominantly of tachycardia, short P-R intervals, broad QRS complexes, deep Q waves, and abnormal P waves Manifestations of congestive heart failure are rarely seen presumably because of the enforced inactivity, however, heart failure may occur suddenly and may be a terminal event in the disease process Since the pathological changes found in the hearts of such patients are identical with those found in skeletal muscle, every patient with progressive muscular dystrophy should be regarded as a potential cardiac patient and should therefore be treated accordingly.

SUMMARY

A number of factors operating primarily outside of the realm of the heart and the great vessels may indirectly influence the work of the heart or may coincidentally involve the heart and so produce symptoms and signs of heart disease As a result, it behooves the clinician to be aware of these various factors and to approach the management of every patient with cardiovascular disease with all of these extracardiac factors in mind

relatively rare in the United States as a result of the general high standard of living and the *widespread use of vitamin supplements in* various food items, such as white bread, the disease still occurs and the possibility of thiamine deficiency in any patient with congestive heart failure should be kept in mind. The criteria for beriberi heart disease set up by Blankenhorn (1946) continue to be applicable. (1) unclear pathogenesis; (2) history of 3 or more months on a thiamine-deficient diet, (3) signs of peripheral neuritis or pellagra; (4) cardiomegaly with sinus rhythm, (5) edema, high venous pressure, anemia, and hypoproteinemia; (6) minimal electrocardiographic changes; and (7) recovery with decrease in heart size following specific therapy.

An unusual variation of beriberi heart disease, *in which acute arterial hypertension de*veloped and congestive heart failure followed, has been described by Walters. It is likely that many atypical cases go unrecognized and, because of inadequate therapy, they may progress to a severe and irreversible stage.

In *cirrhosis of the liver*, the presence of ankle edema, ascites, collateral portal circulation, and vascular spiders, together with a history of an inadequate diet and alcoholism, usually suffice to make the diagnosis. Occasionally, however, manifestations of congestive failure are superimposed upon cirrhosis, and these may go undetected. The heart may be involved in the presence of cirrhosis because of intrinsic myocardial disease or it may be *influenced because of malnutrition and its* allied metabolic defects, the effects of arteriovenous shunts (together with the accompanying increase in blood volume), and the effects of distorted water and electrolyte exchange, perhaps prompted by failure of the diseased liver to inactivate the hormones which normally regulate these moieties. Striking enlargement of the heart and obvious congestive failure, however, are uncommon in patients who have cirrhosis in the absence of underlying heart disease.

The adverse effects of *obesity* in reference to cardiovascular morbidity and mortality are well known and constitute an important factor in the establishment of life-insurance actuarial tables. In recent years, *a reversible cardiopulmonary syndrome associated with extreme obesity* has been described by several authors. This syndrome includes somnolence, cyanosis, polycythemia, periodic breathing, right axis *deviation of the* electrocardiogram, and congestive heart failure. In most instances, patients with this syndrome have weighed over 300 pounds and all symptoms and signs have disappeared following the loss of appropriate amounts of weight.

The exact mechanism by which obesity causes the signs and symptoms of this syndrome are unknown. The limited number of studies which have been performed suggest that pulmonary hypoventilation is produced by the mechanical disadvantage of the obesity and that this, associated with periodic breathing, leads to hypercapnia and hypoxia These in turn result in polycythemia, pulmonary hypertension, right ventricular hypertrophy, and congestive failure. *Although the mech*anisms involved are at present unclear, the clinician should recognize the occurrence of this syndrome and should orient the therapy of the obese patient with these factors in mind

PREGNANCY

Aterations in cardiovascular dynamics which occur during pregnancy may be interpreted as representing a normal physiologic response to the pregnant state. In the patient *with a nor*mal heart, these adjustments produce no ill effects; however, in subjects with underlying heart disease, the physiologic alterations of pregnancy may result in severe and *sometimes fatal congestive* heart failure The circulatory effects of pregnancy may be noted in the second month of gestation and progress gradually to reach a maximum during the thirty-second week. Thereafter, the intensity of these manifestations declines until the time of delivery. Clinically, the effects of pregnancy are manifested by an increased heart rate, palmar flushing, a bounding pulse, capillary pulsations, a prominent apical impulse, and systolic murmurs located at both the apex *and base of the heart* Functional studies performed during pregnancy have demonstrated that oxygen consumption increases by 15 to 20 per cent, cardiac output may increase by as much as 50 per cent, the venous pressure rises, and the retention of sodium and water may result in hemodilution *amounting* to an increase of plasma volume as much as 45 per

her arms of a leaden colour, clammy and cold. She could not lye down in bed and had neither strength nor appetite, but was extremely thirsty. Her stomach, legs, and thighs were greatly swollen, her urine very small in quantity, nor more than a spoonfull at a time, and that very seldom. . . . It is now almost nine years since the Digitalis was first prescribed for this lady, and notwithstanding I have tried every preventive method I could devise, the dropsy still continues to recur at times, but it is never allowed to increase so as to cause much distress, for she occasionally takes the infusion and relieves herself whenever she chooses Since the first exhibition of that medicine, very small doses have been always found sufficient to promote the flow of urine.

CLASSIFICATION OF HEART FAILURE

Attempts have been made to define and describe the limits of the many variations observed among patients who have heart failure. Often the products of these attempts take the form of classifications made from one point of view or another. Overlapping of these classifications has occurred, and it is common to find the several groupings listed end to end, as if each entry represented a different kind of heart disease

Forward and Backward Failure. The beginning of failure, before congestion is recognized and before symptoms are noted, has been the basis of pathophysiologic descriptions

Failure of output is a reduction in the flow of blood to the tissues of the body, called *forward heart failure* More completely, the decreased output exerts the effect of decreasing renal blood flow and the glomerular filtration rate, and producing retention of sodium and thereby of water *This effect probably is accomplished via the adrenal cortex and by means of aldosterone*, but the several steps concerned still are not known The succession of steps leads to *hypervolemia* and subsequently to *edema*[1]

Failure of pumping action is the beginning of the train of events described as *backward failure* (Harrison) According to this concept, the venous return is not adequately handled, and systemic venous engorgement occurs The increased venous pressure opposes the oncotic pressure at the capillary level, leading to edema

The concepts of forward and backward failure are justified to the extent that they emphasize part of the mechanism of the formation of edema The importance of the role of retention of sodium and of hypervolemia has been widely accepted (Davis). The terms "forward" and "backward" are, at times, used as if they described clinically different diseases. Thus, backward failure of the right ventricle would produce systemic venous congestion while backward failure of the left ventricle would produce pulmonary vascular congestion. Even though decreased output and increased atrial pressure (congestion) often occur together, it is possible for one of the two phenomena to predominate or even to occur alone This concept, first advanced by experimental workers,[2] was then confirmed in man through cardiac catheterization (Selzer, 1960).

Myocardial and Mechanical Heart Failure. In hemodynamic terms, *myocardial failure* describes the situation in which there is an increase of the end-diastolic volume of the ventricle because of ventricular dilatation with increase of residual blood There is a decrease in effective systolic emptying. However, there is no predictable relationship between end-diastolic volume and end-diastolic pressure over the range of volume increments (Eddleman). The increase of ventricular end-diastolic pressure is necessarily followed by an increase of pressure in the respective atrium and in the veins that are served by it. Thus, increase of diastolic pressure of the left ventricle results in pulmonary congestion, while increase of diastolic pressure of the right ventricle is followed by systemic congestion Myocardial failure includes states in which the myocardium becomes inadequate, either because of diffuse disease of the myocardium, or as a final stage of the clinical course of valvular or septal defects in which the myocardium becomes hypertrophied

Mechanical heart failure implies production of visceral congestion without necessarily involving failure of the ventricular myocardium. Two types of congestion should be considered separately.

1 Constriction of the ventricular wall from without (constrictive pericarditis), within (fibroelastosis), or in the wall itself (amyloidosis, fibrosis) causes an *increase* of diastolic pressure which is followed by atrial and venous

Clinical aspects of heart failure

MILTON W. ANDERSON AND JOHN A. CALLAHAN

INTRODUCTION

Heart failure represents a clinical syndrome due to diverse causes, as well as faulty function of specific segments of the circulation; therefore, the manifestations of this condition are numerous and varied. Separation of symptoms and signs resulting from the causative lesion from those directly connected with the heart failure may be difficult in some instances. In other situations, individual variations of the adaptative phenomena differ in spite of similar causative factors for the failure syndrome, so that the over-all picture differs from patient to patient.

The manifestations of heart failure may appear different depending upon the criteria for evaluation. The clinician recognizes one set of circumstances as representing the syndrome; the laboratory specialist, who determines values for pressure and flow hemodynamically, would recognize different circumstances. Similarly, varied criteria might be set up by the myocardial biochemist or by the nephrologist, who describes the syndrome as it pertains to the role of the kidneys in readjusting salt and water.

One common denominator is *inadequacy of the circulation in one or more parts of the total body circulation for a given person at a given time.* This means that *the cardiac output is inadequate to meet the demands of the body.* When this happens, prior to the development of the syndrome, certain adaptative phenomena, both neurogenic and humoral, as well as those intrinsic within the heart, will have exhausted their ability to maintain a compensated state. As these mechanisms become exhausted, *the cardiovascular system may be said to have progressively lost its reserve.* In some patients, this reserve may be retained for a long period, even though it may be strained to the limit, if that limit is not exceeded. In other patients, the cardiac reserve may be exhausted rapidly by the superimposition of any of several types of stress, which acutely increase the demands of the body, interfere with the adaptive mechanisms, or further compromise the cardiovascular pump.

In most patients, the onset of the syndrome is gradual. The symptoms are first noted during *exertion* or other stressful situations. The failing heart cannot increase its output to meet the greater requirements of the tissues. Later, a more profoundly inadequate circulation leads to symptoms that are evoked with smaller degrees of activity. Some of the variation in the clinical manifestations is related to the speed of onset of heart failure, the different causes for the failure, and differences in the requirements of the organs producing the symptoms and in the metabolic state of the person

The heart is always involved, but sometimes the condition of the heart may not be the principal cause of the failure, the heart has, however, the role of being the dominant organ It influences the resulting disease and is influenced by it.

The classic account by William Withering (1785) beautifully describes the full-blown picture of the syndrome of heart failure:

> I found her nearly in a state of suffocation, her pulse extremely weak and irregular, her breath very short and laborious, her countenance sunk,

her arms of a leaden colour, clammy and cold. She could not lye down in bed and had neither strength nor appetite, but was extremely thirsty. Her stomach, legs, and thighs were greatly swollen; her urine very small in quantity, nor more than a spoonfull at a time, and that very seldom. . . . It is now almost nine years since the Digitalis was first prescribed for this lady, and notwithstanding I have tried every preventive method I could devise, the dropsy still continues to recur at times, but it is never allowed to increase so as to cause much distress, for she occasionally takes the infusion and relieves herself whenever she chooses. Since the first exhibition of that medicine, very small doses have been always found sufficient to promote the flow of urine

CLASSIFICATION OF HEART FAILURE

Attempts have been made to define and describe the limits of the many variations observed among patients who have heart failure. Often the products of these attempts take the form of classifications made from one point of view or another. Overlapping of these classifications has occurred, and it is common to find the several groupings listed end to end, as if each entry represented a different kind of heart disease

Forward and Backward Failure. The beginning of failure, before congestion is recognized and before symptoms are noted, has been the basis of pathophysiologic descriptions.

Failure of output is a reduction in the flow of blood to the tissues of the body, called *forward heart failure*. More completely, the decreased output exerts the effect of decreasing renal blood flow and the glomerular filtration rate, and producing retention of sodium and thereby of water *This effect probably is accomplished via the adrenal cortex and by means of aldosterone*, but the several steps concerned still are not known The *succession of steps leads to hypervolemia* and subsequently to *edema*.[1]

Failure of pumping action is the beginning of the train of events described as *backward failure* (Harrison) According to this concept, the venous return is not adequately handled, and systemic venous engorgement occurs The increased venous pressure opposes the oncotic pressure at the capillary level, leading to edema.

The concepts of forward and backward failure are justified to the extent that they emphasize part of the mechanism of the formation of edema. The importance of the role of retention of sodium and of hypervolemia has been widely accepted (Davis). The terms "forward" and "backward" are, at times, used as if they described clinically different diseases. Thus, backward failure of the right ventricle would produce systemic venous congestion while backward failure of the left ventricle would produce pulmonary vascular congestion. Even though decreased output and increased atrial pressure (congestion) often occur together, it is possible for one of the two phenomena to predominate or even to occur alone. This concept, first advanced by experimental workers,[2] was then confirmed in man through cardiac catheterization (Selzer, 1960).

Myocardial and Mechanical Heart Failure. In hemodynamic terms, *myocardial failure* describes the situation in which there is an increase of the end-diastolic volume of the ventricle because of ventricular dilatation *with* increase of residual blood. There is a decrease in effective systolic emptying. However, there is no predictable relationship between end-diastolic volume and end-diastolic pressure over the range of volume increments (Eddleman). The increase of ventricular end-diastolic pressure is necessarily followed by an increase of pressure in the respective atrium and in the veins that are served by it. Thus, increase of diastolic pressure of the left ventricle results in pulmonary congestion, while increase of diastolic pressure of the right ventricle is followed by systemic congestion. Myocardial failure includes states in which the myocardium becomes inadequate, either because of diffuse disease of the myocardium, or as a final stage of the clinical course of valvular or septal defects in which the myocardium becomes hypertrophied.

Mechanical heart failure implies production of visceral congestion without necessarily involving failure of the ventricular myocardium Two types of congestion should be considered separately.

1. Constriction of the ventricular wall *from without* (constrictive pericarditis), within (fibroelastosis), or in the wall itself (amyloidosis, fibrosis) causes an increase of diastolic *pressure which is follow*ed by atrial and venous

[1] See Chaps. 3 and 4, this Part. *Editor.*

[2] See Chaps 1 and 2, this Part. *Editor.*

congestion. In the case of the left ventricle, pulmonary hypertension is also a result.

2. The narrowing of one of the AV valves causes rise in pressure in the respective atrium and venous system (*mitral stenosis = left atrial* and pulmonary hypertension; tricuspid stenosis = right atrial and systemic hypertension). The normal level of ventricular pressure of these forms and the pressure gradient that develops across the valve are typical of these lesions.

High-output and Low-output Failure. In the average case of congestive heart failure, cardiac output decreases below the level of output that is normal for the particular patient, and usually well below the average normal output for persons of that particular size.

In contrast to this, there is a group of patients with congestive heart failure who have greater than normal cardiac output. This state has been called *high-output failure, hyperkinetic syndrome with failure,* and *overactive heart.* When these conditions are present, even the increased cardiac output cannot meet the metabolic demands of the body. There may be an increased tissue demand, such as arises in *thyrotoxicosis,* a defect in the transfer system, such as occurs in profound *anemia,* or alterations in volume, such as develop in *hypervolemia* and large *arteriovenous shunts* The situation which exists in the presence of *beriberi heart disease* is still incompletely understood. When beriberi is present, there probably are defects in transport systems and in cellular metabolic systems.

Right-sided and Left-sided Failure. Right-sided failure implies failure predominantly of the right ventricle. This is characterized clinically by an increase in systemic venous pressure, venous congestion, and peripheral edema Left-sided failure implies failure predominantly of the left ventricle, and it produces pulmonary vascular congestion Combined right-sided and left-sided failure produces pulmonary vascular and systemic venous congestion In most cases of congestive heart failure, combined failure of both sides eventually comes about.

Cor Pulmonale. This term describes right ventricular strain and hypertrophy as a result of disease of the lungs, the pulmonary circulation, or both An acute form of this condition exists in the case of acute right ventricular strain after *pulmonary embolism.* In the presence of chronic cor pulmonale, the heart disease is the result of disease of the lungs Certain diseases, like ventricular septal defect with pulmonary hypertension, produce an end-stage condition which is similar to that of cor pulmonale. Often the over-all weight of the heart in the diseases which produce cor pulmonale is small, and the hypertrophy of the right ventricle might be overlooked.

Diseases of the lungs productive of chronic cor pulmonale are those which involve the vessels diffusely, such as primary pulmonary hypertension, multiple thromboses, various kinds of fibrosis, and extravascular processes of infiltration and compression. Other diseases are those accompanied by predominant loss of effective pulmonary volume, such as emphysema, asthma, and chronic bronchitis. One additional group includes alveolar hypoventilation, such as *kyphoscoliosis, neuromuscular disease,* and extreme obesity. Obviously, in one patient emphysema and fibrosis or emphysema and hypoventilation can occur together.

Circulatory Failure. Failure or inadequacy of the circulation may occur as a sudden catastrophic event When this happens, symptoms are produced by a profound decrease in arterial pressure and a sudden deficiency in the perfusion of tissues This action, in itself, is not a part of the congestive syndrome. It belongs in the separate category of *circulatory shock* Shock often occurs among patients who have heart disease, and the terms "cardiac shock" or "postinfarction shock" are applied Such a patient is hypotensive, restless, and obtunded, and exhibits a cold, pale, sweaty skin. Many patients suffering from chronic congestive failure manifest this pattern of a profound shock-like state in the last hours of life. Other patients, who have suffered a severe insult, such as a massive myocardial infarct, may display the peripheral signs of shock and have, at the same time, pulmonary congestion or frank pulmonary edema In "cardiac" or "cardiogenic" shock, the most important cause of the syndrome is the sharply decreased cardiac output However, additional factors are represented by various reflexes and by the presence of tissue substances and hormones in the circulating blood, some of them contributing to the alteration while others are ineffective compensatory phenomena

New York Heart Association Classification. The New York Heart Association classification is built upon severity of disease in individual

patients and does not consider causation or type of disease. Many of the classes of this grouping have no relationship to congestive heart failure The classification consists of four functional classes listed by numbers, and five therapeutic classifications listed by letters. Class I includes patients who have no symptoms, class II includes those whose symptoms appear only on exertion, class III applies to patients who have severe symptoms, such as will permit only little exertion, and class IV includes patients who are incapacitated and bedridden

The functional classification describes the amount of exertion the patient can tolerate The therapeutic classification suggests the amount of exertion the patient should undertake and does not presume to describe detailed therapeutic programs Therapeutic class A refers to a patient whose physical activity need not be restricted. Class B describes patients who may be allowed ordinary exertion, but who should avoid extreme exertion Class C describes patients who should exercise moderation, even in ordinary activities Class D describes patients whose activity should be markedly restricted Class E includes patients who should be at complete rest in bed or in a chair The functional and therapeutic classifications need not be parallel. Thus, a man in the first few days after a myocardial infarct might be classified I, E

CLINICAL SYMPTOMS OF CONGESTIVE HEART FAILURE

In most instances, congestive failure develops slowly, not as the immediate result of a catastrophe The first symptoms are experienced during stressful situations, perhaps severe exertion. Later, as the disease becomes more severe, symptoms are produced as a result of less exertion, and eventually they occur while the victim is at rest. The symptoms of congestion are the direct consequences of deficient output and of compensatory mechanisms which the body employs as a result of the deficient pumping The prominent symptoms are breathlessness, weakness and fatigue, cough, abdominal discomfort, swelling of the dependent portions of the body including the abdomen, and mental symptoms

Dyspnea. Dyspnea, or "shortness of breath," is present when the person is conscious of some difficulty in breathing This is a subjective experience and does not always correlate well with the objective signs of congestive failure Many persons may experience dyspnea and not have congestive heart failure. Normal persons may experience dyspnea as a result of unusual exertion. Persons who have no organic disease can be dyspneic because of anxiety.

Dyspnea in the presence of congestive heart failure first occurs *during exertion* and subsides quickly with rest. In patients who have pulmonary hypertension, the dyspnea may remain during a considerable period of rest. In mitral stenosis and some instances of hypertensive heart disease, the severity of exertional dyspnea may remain the same for long periods, with no significant increase. Eventually, the severity progresses with the onset of failure, and dyspnea comes to be present even during rest

In the lungs, mechanical encroachment is produced by the congestion of blood in the pulmonary capillaries, which occupies space ordinarily used for air. The total capacity of the lungs is reduced, this change being manifested mostly as a *reduction in vital capacity.* The turgor of the congested vessels and probably edema of the interstitial spaces produce increased stiffness (reduced compliance) of the lungs The result is an increased work of breathing. The tense, wet lungs cause *exaggerated responses of the stretch receptors in the lungs* Similar receptors in the right heart and great veins, proprioceptive receptors in the muscles of respiration, and the anxiety and excitement of the patient combine with the pulmonary reflexes to produce an increase in respiratory drive In spite of these situations, the alveoli usually are adequately ventilated and arterial blood in the presence of congestive failure often is adequately oxygenated unless pulmonary edema is already present The factors causing the dyspnea often bring about a respiratory effort which exceeds the actual need Therefore, the use of opiates in extreme dyspnea is both physiologic and effectual.

Orthopnea is an extension of dyspnea, although at times a patient may complain more bitterly of orthopnea than of exertional dyspnea Orthopnea results from an actual increase in pulmonary congestion when the patient lies down. Through increase of venous return, redistribution of the volume of circulating blood takes place when a person lies down. This can be observed to produce a decrease in vital capacity

Pulmonary edema usually is a sudden and

potentially catastrophic event in the course of heart disease. It may occur as the result of (1) a sudden change in dynamics of the previously compensated heart; (2) myocardial infarction; (3) acute left ventricular failure in the presence of hypertension.[3] Pulmonary edema may occur during the course of chronic congestive heart failure; when it does, it most often occurs at night. This action seems to combine the change in vital capacity associated with lying down with a change in cardiac output during sleep. The patient experiences severe dyspnea, cyanosis, coughing productive of frothy, often pink, "edema" fluid, and panic. This state requires prompt treatment, and the measures often are surprisingly effective. A less dramatic form of the same process is *paroxysmal dyspnea.* When pulmonary edema is present, the pressure of the blood in the pulmonary capillaries exceeds the colloid osmotic pressure of the blood, and transudation of fluid occurs through the alveolar-capillary wall into the alveolar space. The wet alveolar membrane and the edema fluid interfere with gas exchange. The edema fluid may become frothy and interfere further with gas exchange.

Coughing often is produced as a result of congested lungs and bronchi, and may be an annoying symptom. It may result from pressure of an enlarged pulmonary artery or its left branch on the trachea or recurrent laryngeal nerve. Coughing often robs the patient of badly needed sleep, and it may precipitate an episode of paroxysmal dyspnea or pulmonary edema

Periodic breathing (*Cheyne-Stokes respirations*), due to hypoxia or reduced cerebral blood flow, may be observed in patients who have congestive heart failure. Yet it is by no means specific, since it may occur in many disease states and in some normal states This term describes an alternation between periods of apnea and hyperpnea, often accompanied by stupor and restlessness. During one of the episodes of periodic hyperpnea, paroxysmal dyspnea or pulmonary edema may be precipitated.

Hemoptysis may occur in variable degree, the quantity of blood ranging from faint staining or streaking of the sputum to fatal hemorrhage. The bleeding might come from engorged pulmonary tissue, bronchial mucosa, or a ruptured blood vessel. Hemoptysis is particularly common when mitral stenosis and heart diseases producing pulmonary hypertension are present, or when bronchial infection is present. Obviously pulmonary embolism, common in the course of congestive failure, may be a cause of hemoptysis.

Abdominal Distress. Gastrointestinal symptoms are common among patients who have congestive heart failure, and occasionally such symptoms may be the presenting manifestations. Pain in the right upper abdominal quadrant or epigastrium is common. This may be the type of pain which arises with exertion or which is felt at rest. Usually the liver is found to be enlarged and tender. Rapid *enlargement of the liver* may be painful, and occasionally it may suggest an acute abdominal emergency. Because of other factors, which are poorly understood, there is no predictable relationship between height of venous pressure and enlargement of the liver or abdominal symptoms

Other abdominal symptoms may include *anorexia, nausea,* and *vomiting* as a result either of engorgement of abdominal viscera or of medication. When *dependent edema* and abdominal enlargement with *ascites* are extensive, the abdominal symptoms may abate after some time, even though the ascites and abdominal engorgement may not be completely relieved. The abdomen seems to possess a certain degree of accommodation to the new state of dysfunction. Usually there is a gradual loss of body tissue which goes unnoticed because of the edema. Over a long period, *cachexia* may be marked.

Edema. The accumulation of edema fluid in the dependent parts of the body is the classical feature of congestive heart failure. Congestive failure was only later separated from the condition manifested by the general group of edematous patients said to have "dropsy." The phrase "edema-laden" sometimes is used to emphasize the picture of wetness and swelling in patients with severe congestive heart failure As a rule the clinical discovery of edema is not difficult Occasionally it is difficult to distinguish *between* the edema of heart disease and that of other origin. Abdominal swelling and ascites sometimes will cause diversion of diagnostic scrutiny away from heart disease.

The problem of edema brings up the ques-

[3] Pulmonary edema is described in detail in Chaps. 10 to 14, this Part *Editor.*

tions, "What is the first event in congestive heart failure? In what sequence does the heart decompensate?" An integral part of these questions is, "What produces the edema?" This problem returns to a consideration of the hypotheses of "backward" and "forward" failure as mentioned above Under the designation "backward" failure, it was contended that the primary event is elevation of venous pressure, elevated capillary pressure, and formation of edema Other factors were acknowledged as contributing to the edema fluid (Barger; Davis and Smith). Under "forward" failure, an attempt was made to emphasize the role of the kidney in the formation of edema. Early in the course of heart failure, increased reabsorption of sodium occurs, primarily as a result of altered cardiac output The mechanism which initiates renal retention of sodium is not clear, but it may involve part of the normal reflex and humoral adjustments for the maintenance of blood pressure An important role certainly is played by *aldosterone*, with a direct effect on the renal tubular transport of sodium, and therefore of water (Davis).*

Cerebral Symptoms. Symptoms of cerebral dysfunction are parts of the advanced stages of congestive heart failure These occur late in the progression of decompensation of the heart, but such a sequence might require only a relatively short time in cases of serious and rapidly advancing disease, such as massive myocardial infarction The symptoms are those of inadequate perfusion of the brain, probably combined with more *complicated* secondary effects of inadequate perfusion of other organs of the body Mild changes in personality and periods of confusion and disorientation appear relatively earlier Restlessness, stupor, and coma may precede death These symptoms are profoundly influenced by many medications used in the treatment of congestive heart failure It would be well to review therapy carefully if a change in the state of consciousness or behavior *develops*.

CLINICAL SIGNS OF CONGESTIVE HEART FAILURE

The causes of congestive heart failure are varied This fact is influential in producing the first manifestations of congestive heart failure in different chambers. It is thereby possible to relate certain clinical observations to failure of specific cardiac chambers, especially in the early course of the syndrome. Traditionally, clinicians divided congestive heart failure into *left heart failure* and *right heart failure*. Synonyms of left heart failure also are the terms, "left ventricular failure" and "left-sided heart failure." Similar expressions have been applied to failure limited to the right side of the heart. A more exact classification and interpretation of the clinical aspects of congestive heart failure are possible when the hemodynamic abnormalities producing these findings are related to the specific chamber in which the pumping function is impaired. This concept appears valuable, even though it is immediately apparent that it is rare for the syndrome of congestive heart failure to be caused by failure limited to one chamber. Hence, this section will be confined to a description of the clinical signs and findings as they appear to the examiner at the bedside.

Left Ventricular Failure. Failure of adequate left ventricular output may occur acutely secondary to massive infarction, acute inflammatory myocardial disease, or sudden inadequacy of the aortic or mitral valves. This type of failure occurs *less dramatically* after progressive hypertrophy secondary to (1) systemic arterial hypertension, (2) stenosis and regurgitation of the aortic valve, (3) mitral valvular regurgitation, or (4) less acute loss of myocardial function as a result of coronary atherosclerosis or myocarditis.

Clinical examination of the patient who has left ventricular failure readily yields indications of an abnormal cardiac status as well as abnormality in areas remote to the heart Hypertrophy and dilatation of the left ventricle are detected by palpation of a sharp apex impulse lateral to the left midclavicular line Percussion of the precordium will confirm a broad area of cardiac dullness, sometimes extending to the left midaxillary line *In* the presence of both acute and chronic left ventricular failure, a *diastolic gallop rhythm* frequently is heard at the apex [Fig 18-4(1)], the 3d, or adventitious, *heart sound* appearing at the time of rapid ventricular filling Functional incompetency of the mitral valve related to left ventricular enlargement, with dilatation of the mitral valve ring, frequently is responsible for a *blowing apical systolic murmur* Extracardiac evidence of left ventricular failure also may be

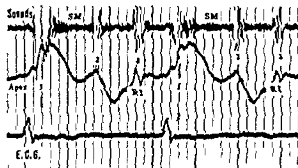

Fig. 18-4(1). Protodiastolic gallop sound (3) occurring between the 2d sound (2) and the 1st sound (1). This coincides with the rapid inflow wave (RI) of the apex linear cardiogram. The soft decrescendo systolic murmur (SM) of mitral insufficiency is noted. This electrocardiogram demonstrates atrial fibrillation.

noted. Peripheral cyanosis related to increased difference in arteriovenous oxygen saturation is especially observed in the presence of acute left ventricular failure when cardiac output decreases rapidly. The peripheral pulses usually are rapid and thready, and *pulsus alternans* can be demonstrated when left ventricular myocardial function is severely impaired. Pulsus alternans is detected as an alternately strong and weak impact against the examining fingers palpating the peripheral pulse in the presence of a regular cardiac rhythm. Left ventricular failure manifests itself most dramatically by *congestion of the lungs* on the basis of simultaneous left atrial failure.

As a consequence of any acute or chronic etiologic factor, when left ventricular diastolic pressure increases, a similar increase in pressure must ensue in the left atrium to maintain a left atrioventricular filling gradient. The increased blood volume and consequent pressure are reflected back to produce pulmonary venous and pulmonary capillary hypertension. As indicated before, more blood pooled in the lungs will reduce the compliance and air capacity of these structures. At the point at which the pulmonary capillary pressure exceeds that of the colloid osmotic pressure, transudation into the lungs and pleural spaces takes place.

Characteristically, the patient who has uncontrolled and overt left ventricular failure assumes a sitting position in bed, and often will rest on his hands to hyperextend the thoracic sector of the spinal column. He complains of suffocation when he is in a recumbent position. His breathing is rapid and labored, and he uses accessory muscles to increase respiratory excursions. These signs, orthopnea and tachypnea, are first noted in response to unusual effort or emotion, and they will subside as the stressful situation ceases. When the clinical state is severe and acute pulmonary edema develops, a fulminating picture presents itself. The patient will be cyanotic and restless and will perspire profusely; his breathing will be extremely rapid, punctuated by frequent coughing, which often is productive of copious amounts of frothy and blood-stained sputum.

Usually, a *rapid heart rate* is present. *Atrial fibrillation* often is the rhythm in patients whose causative lesion is deformity of the mitral valve, as well as in a high percentage of patients who have advanced left ventricular failure arising from other causes. Generally, the *2d cardiac sound* in the pulmonic area will be characterized by increased splitting and accentuation of the pulmonic component. Results of auscultation over the fields of the lungs vary greatly, depending upon the stage of the congestive syndrome. There may be essentially normal breath sounds, despite an increased respiratory rate. When left ventricular failure is chronic and mild, *fine moist rales* limited to the lower segments of the lungs are the rule.

Musical and sibilant rales heard diffusely in all areas, especially in the expiratory phase of respiration, are characteristic of the acute pulmonary congestion which manifests itself as *paroxysmal dyspnea* (older term: *cardiac asthma*). This clinical picture may mimic closely that of bronchial asthma unless additional diagnostic signs are at hand.

In chronic failure of the left heart, which is associated with pleural effusion, the breath sounds over the sites of the retained serous collections will be diminished or absent, and the percussion note will be flat. Acute pulmonary edema presents the listener with a multitude of sounds, including moist rales, expiratory wheezes, and coarse, bubbling rales and rhonchi from tracheal secretions.

Roentgenograms of patients who have left ventricular failure will show a diversity of pathologic changes.[5] Characteristically, enlargement of the left atrium is present as a significant abnormal feature of the cardiac silhouette when mitral valvular disease is at

[5] See Chap. 8, this Part. *Editor*

hand, and, to a lesser extent, when the morbid state is left ventricular failure without primary mitral disease Chronic pulmonary venous hypertension, like mitral stenosis, frequently is accompanied by the roentgenographic demonstration of costophrenic septal lines. The pulmonary fields show variable evidence for the congestive changes that exist [Fig. 18-4(2)]. *Hilar vascular congestion* is seen routinely and extends to cast bilateral central infiltrative shadows when pulmonary edema also is present Bizarre forms of pulmonary congestion, which may be limited to one lung or to one aspect of one lung, may cause left ventricular failure to be confused with other pulmonary pathologic processes, such as neoplasm or inflammation [Figs. 18-4(3 and 4)]. Similarly, the occurrence of serous effusions may be limited, and the effusive processes may be located at sites which make a differential diagnosis difficult.

Perhaps the only specific electrocardiographic abnormality attributed solely to left atrial enlargement is the appearance of broad P waves of increased amplitude in both the extremity and precordial leads The electrocardiogram also may confirm the presence of atrial fibrillation and will reflect left ventricular hypertrophy, necrosis, or other abnormality, such as conduction disturbance, when the causative lesion has primarily affected the left ventricular myocardium Right ventricular and right atrial enlargement also may be observed in chronic left heart failure, which produces right ventricular hypertrophy and, finally, right ventricular failure. All these electrocardiographic abnormalities also may be present to some extent in patients whose condition has not reached the decompensated state, so that they do not make it possible to assume the presence of congestive failure. *Electrical alternans*, on the other hand, is an infrequent electrocardiographic finding that correlates highly with left ventricular failure [Fig 18-4(5)]. This phenomenon exhibits itself by alternate ventricular complexes of either greater amplitude or greater duration in the presence of sinus rhythm.

Right Ventricular Failure. Elevated right ventricular diastolic pressure, which is the salient evidence of right ventricular failure, most frequently results from left ventricular failure, which has interfered with forward flow from the right ventricle. Right ventricular failure occurs as a primary event on the basis of outflow obstruction caused by both pulmonary valvular obstruction and pulmonary vascular disease, which increases resistance to right ventricular outflow Acute right ventricular failure arising from *embolization of the pulmonary arteries* is dramatic when severe, and characteristically is featured by tachypnea, diaphoresis, restlessness, systemic hypotension, and cyanosis The clinical picture resembles that of acute hypoxia, which indeed is present If death is not immediate, with massive pulmo-

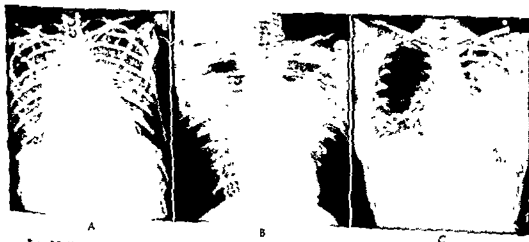

Fig 18-4(2) Roentgenologic manifestations of *pulmonary edema* A. Bilateral involvement, generalized throughout both pulmonary fields, usual type B Bilateral involvement, limited to the upper parts of the pulmonary fields, "bat's wing" or "angel's wing" distribution C. Unilateral involvement.

nary embolism, signs of right ventricular dilatation and acute pulmonary hypertension will appear. The observations include palpable and visible pulsation over the pulmonary artery in the 2d interspace in the left parasternal line. A *pulmonic systolic murmur* and increased amplitude and splitting of the 2d heart sound are heard in the same area The roentgenographic and electrocardiographic findings which suggest acute cor pulmonale appear in other sections of this publication [6]

Chronic right ventricular failure may predominate over left ventricular failure in patients who have generalized myocardial disease, such as thyrotoxic heart disease, myocarditis, or infiltrative myocardiopathies Right ventricular failure occurs exclusive of left ventricular failure on a "mechanical" basis as a result of the overwork resulting from prolonged severe volume overload associated with congenital septal defects, or the pressure overload imposed by pulmonic valvular or infundibular stenosis or pulmonary hypertension. When right ventricular failure is superimposed on preexisting left ventricular failure, amelioration of distressing pulmonary symptoms and findings will ensue, presumably reflecting reduced right ventricular output, which is more readily accepted by the failing left ventricle

The signs of chronic right ventricular failure include evidence of hypertrophy and dilatation of that chamber Since the structure is anteriorly located, there will be widening of the area of cardiac dullness upon percussion, and a diffuse precordial heave will be both palpable and visible Frequently, as in left ventricular failure, a diastolic gallop sound is heard at the time of rapid ventricular filling in the 3rd left interspace near the sternum or over the xyphoid A *systolic murmur* produced by tricuspid regurgitation, when that valve becomes incompetent, is best heard over the lower part of the sternum and at the left parasternal area The murmur characteristically is louder in full inspiration (Rivero Carvallo).

Inability of the right ventricle to accept venous return, which is augmented by hypervolemia secondary to the renal mechanisms for retention of salt and water, produces peripheral signs The veins of the neck are distended with blood, even with the patient in a sitting position, indicating greater venous volume and

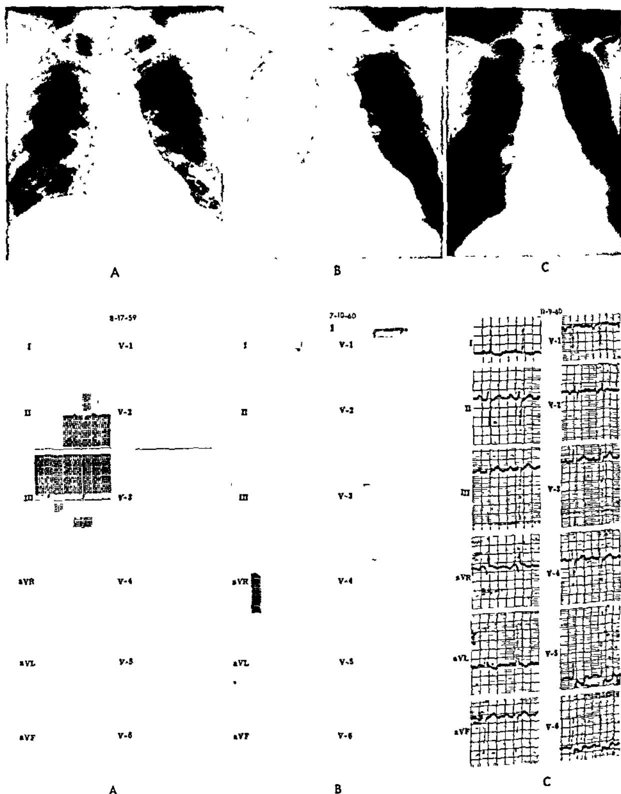

Fig. 18-4(6). Evaluation of congestive heart failure. Pairs of representative roentgenograms and electrocardiograms made from a 62-year-old man who experienced the sudden onset of free aortic regurgitation. A. Acute pulmonary congestive changes and small pleural effusions present about 1 month after the onset of the symptoms of acute dyspnea and hemoptysis The cardiac silhouette was small and the electrocardiogram was normal at this time. B The same patient about 10 months later, when his clinical state had become stabilized by medical management. The roentgenogram has shown moderate enlargement of the cardiac silhouette, with prominence of the left ventricle. The pulmonary fields are now free of visible congestion in the roentgenogram. The electrocardiogram demonstrates increasing left axial deviation and left ventricular hypertrophy plus the effects of digitalis. C Roentgenogram and electrocardiogram made approxi-

monary disease which causes arterial anoxia, *mixed cyanosis* occurs, it may be extreme.

Signs of dropsy in the presence of congestive heart failure usually denote right ventricular failure, but a similar picture occurs in obstruction of the tricuspid orifice secondary to tricuspid stenosis or atresia or to right atrial tumors A similar clinical picture may also be produced by chronic constrictive pericarditis, pericardial effusion, or neoplasms, which selectively interfere with venous return to the right heart

There will be a total decrease in effective cardiac output, which initiates the well-known retention of fluid characteristic of the dropsical state Venous pressure is increased at first intermittently, with periods of increased cardiac work, but finally constantly as myocardial function deteriorates further. Prior to overt failure of the right heart, manual pressure over the engorged liver will visibly distend the veins in the neck, indicating inability of the right atrium to accept a greater return This is called the *hepatojugular reflux* Venous hypervolemia that cannot be accepted by the right atrium causes increased venous pressure The elevated venous pressure interferes with normal osmotic gradients in the systemic capillary beds, causing extracellular accumulation of fluid

The first clinically recognizable features are a *gain in weight* and a *decrease in the output of urine* Only later, after considerable gain in weight, does *edema* become evident at clinical examination in the form of pitting of the extremities The venous and capillary bed are filled to a higher pressure and, in a sense, edema in the tissues aggravates the tension in venous channels by increasing the rigidity of the tissues The increased venous pressure causes or helps perpetuate the edema Thus, the edema and venous pressure are both cause and effect, once the decompensation is under way When effective treatment is instituted, venous pressure remains elevated above normal until diuresis brings about a reduction in blood volume

Peripheral edema is first noted about the shoe tops of the ambulatory patient at the end of the day, and will disappear overnight as a result of nocturnal diuresis or redistribution A similar type of edema of the pitting variety may appear first over the sacrum, buttocks, and thighs, or will be indicated by deep grooves made by the pressure of clothing over dependent parts of the body in the case of bedfast patients Later, this edema may proceed to generalized *anasarca*, with massive subcutaneous collections of fluid in the legs, genitals, lower abdominal walls, and even in the arms and hands, if they remain dependent much of the time The edema is typically soft, it dents under pressure and is painless, but it may be accompanied by oozing, even through the intact tightly stretched skin, when the condition is extreme. Selective accumulations of fluid in serous cavities are common, although the reasons for the selective site in individual patients remain obscure. Characteristically, *ascites*, which may at times be massive, is seen more frequently in constrictive pericarditis and tricuspid obstructive lesions than in generalized heart failure which originates in the left ventricle. The accumulation of *serous effusions* in the pleural spaces and also in the pericardial sac will intensify already impaired pulmonary ventilation and cardiac inflow and output, so that removal of these collections frequently will ameliorate symptoms

The liver becomes enlarged early in the course of right heart failure. The size and tenderness of the structure vary with the state of congestion Prolonged *congestive hepatomegaly* and also sudden insult to the liver occurring in acute congestion will cause jaundice in some patients A combination of icterus and peripheral cyanosis produces a distinctive discoloration of the skin in patients who have congestive failure caused by tricuspid stenosis These patients are found to have direct-reacting hyperbilirubinemia, as opposed to the infrequent appearance of the "retention" type of jaundice which may accompany pulmonary infarction complicating congestive heart failure When right heart failure is of long duration, *splenomegaly* also may be present.

Combined Failure of Left and Right Sides of Heart. A multiplicity of signs indicating that congestive failure has involved both the left side and right side of the heart most often is encountered clinically. Any attempt to outline

mately 18 months after the onset of illness and 1 month prior to death. There is now full-blown right and left heart failure The cardiac shadow is now markedly enlarged in all chambers, and the electrocardiogram shows further progression of the left ventricular hypertrophy pattern.

The blood in heart failure

STEPHEN C. MATHEWSON AND MARIO STEFANINI

The clinical findings and the blood changes encountered in patients with heart failure are the final effects of several major mechanisms. The decline in contractile energy of the myocardium leads to dilatation of the cardiac chambers, increased residual blood volume, and elevation of the intraventricular end-diastolic pressure. Changes in venous pressure and in the distribution of blood in various parts of the body follow promptly. The alterations in the pulmonary and systemic circuits often result in congestion and edema, and lead finally to increased volume of blood, and of interstitial and perhaps intracellular fluid. Irrespective of right-sided or left-sided failure, the circulation time becomes prolonged and tissues become hypoxic.[1]

Hypoxia and, especially in right ventricular failure, the elevation of venous pressure, probably lead to sodium retention by the kidney because of decreased renal blood flow and decreased glomerular filtration rate. More active secretion of aldosterone and desoxycorticosterone by the hypoxic adrenal gland may also contribute to increased tubular reabsorption of sodium. Finally, the hypothalamus may secrete greater quantities of antidiuretic hormone. It is perhaps significant in this respect that substances inducing retention of salt are, in fact, found in the urine of patients with congestive heart failure (Singer and Wener). Hypoxia also stimulates the bone marrow, possibly through increased production of erythropoietin by the kidney and other organs. It also affects adversely the nutritional status of the vascular intima, lesions of which may lead to increased incidence of venous and arterial thrombosis. The liver, because of its proximity to the right atrium, bears the first brunt of right-sided heart failure. Its congestion is often more marked than that of other organs (Popper and Schaffner).[2] The hepatic involvement may lead to deficient protein synthesis involving albumin and, occasionally, some of the coagulation factors and it will be discussed later. Thus, the effects of hypoxia are of great complexity because of the functional involvement of many organs.

The hematologic changes observed in congestive heart failure are of a wide variety. They are apt to be more pronounced when congestion follows constrictive pericarditis or tricuspid valve disease. In such cases, the rise in the peripheral venous pressure is greater and severe hepatic involvement is more frequently found. On the other hand, hematologic changes are less severe when the failure of the right ventricle follows failure of the left; and this condition is more commonly seen. The pathogenesis of the hematologic changes in heart failure is, in most instances, of difficult interpre-

[1] Because of the dissociation properties of oxyhemoglobin, *the arterial oxygen tension*, which is considerably decreased, is a better indication of hypoxia than oxygen saturation of peripheral blood, ...ly slightly decreased.

[2] The severe hypoxia does not necessarily imply failure of function. In fact, needle biopsies of the liver in thirty patients with varying degrees of heart failure due to a variety of causes have shown no correlation between histological changes, severity and duration of the heart failure, and the results of liver function tests (White et al.).

signs without including the symptomatology of heart failure and without excluding features peculiar to the specific cause is faulty, but it appeared to be justified in the foregoing paragraphs to bring about a better understanding of the whole syndrome.

Roentgenograms of the thorax and electrocardiograms made during examination of a man 62 years old are illustrated in Fig 18-4(6). They demonstrate the evolution of the total syndrome of congestive heart failure, beginning with left ventricular failure secondary to acutely acquired aortic valvular regurgitation. Initially, this patient experienced hemoptysis and severe recurring pulmonary congestion characterized by tachypnea, orthopnea, and the physical signs of pulmonary edema. Progressive left ventricular hypertrophy became evident electrocardiographically as well as in the roentgenograms His clinical state was then stabilized for several months. The observed improvement was short-lived, however, and once more left ventricular dilatation developed, accompanied by functional mitral regurgitation It was followed by right ventricular failure The latter manifested itself prior to death, and was accompanied by hepatomegaly and generalized anasarca.

THERAPY

The treatment of congestive heart failure is reviewed in detail elsewhere [7] but, since it has a profound influence on symptoms, will be mentioned here The early use of digitalis by Withering, as noted above, profoundly altered *the symptoms and appearance of his patient.* The therapeutic measures in use today are effective and are responsible for a changed course in patients who have congestive heart failure. It is now possible to maintain patients in a state of supported compensation, but the classical state of sodden swelling may return quickly if treatment is stopped Under treatment, patients may function efficiently, but they subsist in a state of buttressed normalcy, and patient and physician must remember the extent of this state of dependence A patient often can be maintained in an edema-free state until the very late stages of heart disease, and he may escape, for some time at least, the consequences of chronic congestion The patient who has congestive heart failure ought to have the benefits of a short instruction program on the nature of his illness and the properties of his medications. It is hoped that he will also come to know the names of the medications. This type of instruction is far from universal. Some patients stop the use of medication as soon as they improve. Others are inadequately treated and are allowed to retain a greater or lesser amount of edema as a chronic situation Any patient, even one who is under the most careful scrutiny, might experience a change in his total state at some time. Actually, the course of congestive heart failure and the appearance and disappearance of symptoms deserve closer scrutiny than they did before effective therapy became available. When a new symptom appears or a new difficulty is encountered, the whole therapeutic regimen should be reviewed The physician should ask himself, "Is this a new development in the course of the disease, or has this been produced by medication?" He should also ask, "Is there any curable basic or contributing disease, the curing of which might relieve or ameliorate the congestive heart failure?"

[7] *See Chap 15, this Part Editor*

ure has subsided If bleeding develops, higher and more sustained doses of vitamin K are needed to counteract the hypoprothrombinemic effect of Dicumarol and analogs

On the other hand, *thromboembolic phenomena are common in patients with congestive heart failure* In a recent series, thromboembolic manifestations were found at autopsy in 30 per cent of 565 patients with congestive heart failure due to rheumatic heart disease (Griffith et al) A reverse study (Hampton and Castleman) indicates that 30 per cent of 370 autopsied patients who showed significant pulmonary embolization had suffered from heart disease, often with congestive failure These results are not surprising Many of the factors mentioned previously may precipitate venous thrombosis in congestive heart failure. They include slowing of blood flow with prolongation of the circulation time, hypervolemia, increased venous pressure, high blood viscosity linked to the high red cell mass, and others Their combined effect leads to stagnation of blood within the veins and, thus, to local hypoxia Endothelial damage follows, in the authors' opinion one of the major factors in venous thrombosis This picture becomes exaggerated in bedridden patients Clinicians are aware of the frequent formation of clots within the veins of the lower limbs in these patients, clots from which thrombi may extend proximally in the direction of the venous flow and achieve considerable length before severe embolism occurs In fact, repeated episodes of pulmonary embolization may occur without any or with only circumstantial evidence It is of interest that pulmonary embolization may be suspected in patients with congestive heart failure purely on the basis of a hematologic finding, *the sudden appearance of normoblasts in the peripheral blood.* Recently, the authors have become aware of a syndrome which also seems to bear relation to the occurrence of pulmonary embolization during congestive heart failure. The syndrome refers to patients whose congestive heart failure is rapidly progressive and resistant to digitalization, even at or near toxic doses, or to mercurial diuretics (Tench) The ligation of the superficial femoral veins in these patients, even when there is no clinical evidence of peripheral thrombosis, may be followed by a striking diuretic response It would seem that there is, in these cases, a continuous seeding of the pulmonary vascular tree with multiple, small emboli responsible for intractable heart failure, a process which is reversed by the ligation of veins.

An equally interesting aspect of intravascular clotting in congestive heart failure is *the occurrence of mural thrombi in the left atrial cavity* with consequent systemic arterial embolization The opposite, of course, also occurs In a published series, at least 30 per cent of patients with rheumatic heart disease, atrial fibrillation or mitral valve disease (or both), and arterial embolization presented some degree of congestive heart failure (Daley et al.). Like cyanotic congenital heart disease, congestive heart failure sees the frequent occurrence of thrombotic as well as (more rarely) hemorrhagic manifestations Both conditions are accompanied by significant and important changes in the formed elements of the blood and in the protein composition of plasma. The discussion presented in this chapter emphasizes the fact that the mechanism of these changes is quite complex and, at least in part, obscure.

tation primarily because of widespread *ignorance of the mechanisms involved in the control* of human hematopoiesis. Studies with dye and radioactive techniques (Schreiber et al.) *concur to indicate that the total blood volume is greatly increased in congestive heart failure.* This increment involves both red cell mass and *plasma volume but the extravascular volume is* also greatly increased. In fact, while the increase in plasma volume hardly ever surpasses *50 per cent or so, the volume of interstitial fluid* may often be doubled. The increase in plasma volume is, as mentioned, probably related to *the retention of salts and fluids* The stimulus for the increased red cell mass is probably the effect of tissue hypoxia (Part 6, Chap 8). *These* abnormalities *tend* to return to normal as the heart compensates, spontaneously or because of therapy The bone marrow appears *hyperactive. There is hyperplasia of all series,* especially of the erythroid elements More mature elements predominate The overactivity of *the bone marrow is reflected in* changes of the formed elements in the peripheral blood Hemoglobin level, red blood cell count, and hematocrit *reading are elevated to* various degrees Reticulocytes are higher than normal (1 to 2 per cent), while orthochromatic and polychro*matophilic normoblasts may be found in the* peripheral blood There is leucocytosis with neutrophilia and moderate shift to the left of *the granulocytic series. Slight thrombocytosis is* found in a majority of cases while thrombocytopenia is found only occasionally The blood *sedimentation rate is elevated (McGinnis et al)* unless the red cell mass is considerably increased, in which case the value may be very low In the authors' experience at least, RBC survival times determined with Ashby's technique have been normal in a majority of cases. Slight increase in urinary and fecal urobilinogen and moderate elevation of the indirectly reacting bilirubin may be found Associated as they are with normal RBC survival time and elevated retention of BSP, these findings probably indicate *moderate liver dysfunction* because of congestion and hypoxia. Blood ammonia level may be high and, thus, account for a variety of mental symptoms occasionally found in patients in failure (Bessman and Evans). Total serum proteins and albumin fraction are often decreased, and the albumin/globulin ratio may be inverted. These changes are probably related to the poor nutritional status, the decreased protein synthesis by a hypoxic liver and, when present, peripheral edema and formation of effusions. Relative increases in gamma and beta globulin fractions are reflected by the occasional positivity of the cephalin-flocculation and thymol-turbidity tests. Serum *alkaline* phosphatase may also be elevated. There is no general agreement or uniformity of findings with regard to the behavior of the *clotting* factors in congestive heart failure. The concentration or activity of most clotting factors is usually normal, more rarely, it is increased Significant fibrinogenopenia and deficiency of labile factor, less pronounced hypoprothrombinemia, and deficiency of stable factors are occasionally *encountered in the* course of congestive heart failure. They have a complex pathogenesis. A factor in their de*velopment is the poor synthesis of coagulation* agents because of functional involvement of the liver. Another is, possibly, the extensive intravascular *coagulation that may occur* in congestive heart failure due to various factors, particularly within the pulmonary district. *Intravascular clotting means* utilization and depletion of circulating clotting factors Thus, at times, a paradoxical combination of *hypocoagulability of the blood* and of *intravascular clotting* is observed Further evidence for a process of intravascular clotting in these pa*tients is the finding* that the patient's serum may contain a factor which accelerates the formation of plasma thromboplastin

In any case, as compared to congenital cyanotic heart disease, spontaneous bleeding manifestations are rare in congestive heart failure, even during and after surgical procedures The one exception comprises patients who have developed severe polycythemia In such cases, the same factors which have been described for congenital heart disease come into play, and significant bleeding may be encountered Another practical consideration refers to the use of "anticoagulant" therapy with "antiprothrombin agents" *Patients with congestive heart failure and hepatic congestion are highly sensitive to the effects of Dicumarol and analogs, possibly because of the slow rate of synthesis of clotting factors by a hypoxic liver* Thus, these drugs should be used cautiously and with careful control of the plasma prothrombin time until such time as heart fail-

than to suspected masked hyperthyroidism for which no laboratory confirmation could be definitely ascertained [1]

Universal Heart Failure (Right and Left Heart Failure). In the course of left-sided heart failure, the right ventricle may become fatigued for a variety of causes which include augmented work due to increased pulmonary resistance, pulmonary hypertension, and hypoxia; then right ventricular failure, as evidenced by subjective symptoms and by a characteristic venous pressure curve, develops The circulation times with ether (to measure the "arm-to-lung" time), with Decholin, calcium, or saccharin (to measure the "arm-to-tongue" time), and with carbon dioxide or nitrogen inhalation (to measure "lung-to-systemic capillaries" time) will reveal the presence of universal retardation of flow in all segments of the lungs However, there are many exceptions, especially as they concern the measurement of the "arm-to-lung" time In a considerable number of cases including hypertensive, arteriosclerotic, rheumatic, and luetic disease, the "arm-to-lung" time has been normal despite the presence of frank right heart failure with a high venous pressure and a positive hepatojugular reflux The "arm-to-tongue" time and the "lung-to-tongue" time (the saccharin time–ether time difference) were invariably prolonged

In a general way, circulation-time studies in congestive heart failure have proved of value in the evaluation of predominant retardation of flow in certain segments of the circulation Unless it can be established that a prolonged circulation time may represent improper mixing and dilution of the test substance in the increased residual blood of a dilated heart, the increased circulation time or the reduced speed of blood flow must be regarded as indicating heart failure which results from a slowing of blood flow in the distended intrathoracic vessels and in the dilated cardiac chambers. Added to this significant factor must be that of the diminished force of the heart which is revealed by diminished cardiac output.

[1] Increased circulation speed has been found by others in cases of pulmonary edema and explained as the result of stimulation of sympathetic centers Actually, this increase may be the determining cause of pulmonary edema because it provokes a "relative" failure of the left ventricle *Editor*

Right Heart Failure. In right heart failure secondary to extensive bronchopulmonary disease, the "arm-to-lung" time is invariably increased (10 to 18 sec), but strangely enough, in some instances is at the upper limit of normal (8 sec). In all these cases, the "arm-to-tongue" time may be increased depending, of course, upon the degree of retardation of blood flow in the arm-to-lung segment. The "lung-to-tongue" time is usually normal (from 5 to 10 sec) which indicates that the functional integrity of the left heart is undisturbed There are rare instances in which, because of severe hypoxia and coronary insufficiency, the left side of the heart becomes functionally handicapped. Consequently, impaired left ventricular function may result as the outcome of long-standing right heart failure. Under such conditions, both the "arm-to-lung" time and the "lung-to-tongue" time yield abnormally prolonged circulation times

There are cases of *decompensated cor pulmonale* of various origins which, in the end stage of chronic pulmonary insufficiency, present considerable interest from the standpoint of circulation-time measurement. The patients, who appear gravely ill, are usually admitted to the hospital as emergencies because of acute bronchopulmonary infections. The clinical features are intense cyanosis, polycythemia, dyspnea, and congestive failure. The circulation times with ether and Decholin seem in marked contrast with those obtained in less critically ill cardiac patients who yield circulation times more markedly prolonged Thus, the "arm-to-lung" time in a "black cardiac" may range from 10 to 16 sec while the "lung-to-tongue" time will yield a reading which is within the normal range of 6 to 10 sec, indicating a predominant right heart failure

7

Circulation times in heart failure

WILLIAM M. HITZIG

AVERAGE TYPE OF CONGESTIVE HEART FAILURE (LOW OUTPUT FAILURE)

The circulation time measured through the lungs in congestive heart failure is invariably prolonged because of the increase in the size of the intrathoracic vascular bed (*i.e.*, the volume of blood in the heart and lungs) and because there is a decline in cardiac output. The degree of prolongation is proportional to the size of the bed In general, it may be said that, the more prolonged the circulation time, the more seriously ill is the cardiac patient. However, this is not universally true. Not infrequently, the patients with cardiac disease who appear most ill are those, suffering from decompensated cor pulmonale, who have circulation times which have been less prolonged than those in patients who appeared less gravely ill but in whom the circulation time measurements showed more extreme deviations from the normal.

Left Heart Failure. In left heart failure, the "arm-to-lung" time may be within normal range whereas the "lung-to-tongue" time is almost always prolonged, sometimes to three times the normal value. *This shows that the prolongation of the "arm-to-tongue" time is localized to the section of the left heart or that the retardation is due to slowing of pulmonary blood flow downstream to the arterial capillaries of the lung (lung-to-tongue segment).* In such cases of isolated left ventricular failure, the normal systemic venous pressure curve and the normal "arm-to-lung" time testify to the functional efficiency of the right ventricle at rest. In other cases, however, even though the venous pressure curve may remain within normal limits, the ether time may be moderately prolonged, occasionally reaching as high as 14 to 16 sec. This may occur particularly when left ventricular failure is severe, the left ventricle and atrium are severely dilated, and pulmonary engorgement is pronounced This bilateral retardation of blood flow, as measured by the circulation-time methods mentioned above, involves both the right and left ventricular units, and reveals thereby a uniformly inadequate or widened cardiopulmonary pathway. The abnormal ether time ("arm-to-lung" time) in such instances may already be significant of "incipient" failure of the right side of the heart. It indicates that, although the right ventricle is able to maintain a normal systemic venous pressure, it is unable to maintain a normal blood velocity through the widened circulatory pathways of the lungs. On the other hand, the prolongation of the "arm-to-tongue" time does not always parallel the severity of the other symptoms of left ventricular failure. In exceptional cases, the "arm-to-tongue" and the "arm-to-lung" time may be within normal limits despite severe symptoms of left ventricular failure Such paradoxical findings were encountered by the author in two cases of pulmonary edema suffering from malignant hypertension. Normal venous pressure was present but there was no explanation for the inconsistency with the clinical picture. There was no anemia or arteriovenous fistula, or other findings consistent with high output failure. A marked tachycardia was present in both instances but this was attributable to heart failure rather

of the high resistance type The vascular dilatation may start in the pulmonary veins, as is the case in early mitral stenosis *In conditions of pulmonary vascular engorgement, the lung markings are well defined and the lung fields are clear* None of these alterations indicate cardiac decompensation, rather, they may express increased filling and elevated pressure on the arterial or venous side as regulatory phenomena If the stasis, however, extends into the smaller vessels (arterioles, venules, and capillaries) which cannot be seen as individual shadow bands, general haziness will cover the entire lung field This condition is usually no longer distinguishable roentgenologically from pulmonary congestion with extravasation of fluid into the pulmonary tissue.

PULMONARY CONGESTION AND SLOWLY DEVELOPING EDEMA

The vascular trunks become still wider, an irregular fine network covers the greater portion of the lung fields and extends to the periphery, *Kerley lines C;* the general haziness increases, particularly in the lower lung fields, while the apical regions are much less involved The vascular shadows lose their distinct contours The hilar shadows become still bigger,

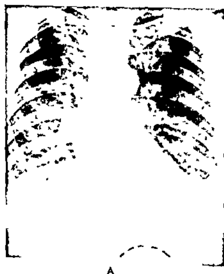

Fig 18-5. *Pulmonary* congestion and edema in heart failure A Man, aged 69 years, with precordial pain and no history of myocardial infarction *The hilar* shadows are irregularly increased, *streaky blotchy* shadows extend to the bases, leaving the upper halves of the lung fields clear Considerable pleural effusion drowns the lower portions of the *heart. On the left,* the large distance between the *gastric gas* and the clear lung indicates the large amount of effusion After 2 weeks of bed rest and proper treatment, lung and pleura *were dry.* B. *Man,* aged 42 years, first diagnosed *as a case* of pneumoconiosis in a man with dust exposure *Mitral stenosis* was eventually diagnosed Chronic small *patchy edema* was almost evenly distributed, only the right lower segment is shown close up Also several horizontal septal *lines (interlobular* edema) are visible No rales were *heard After* mitral valvuloplasty, the lung became perfectly clear.

Roentgenology in heart failure

FELIX G. FLEISCHNER

The terms "chronic lung stasis" (Cooly and Sloan), "central congestion" (Sylla-Zdansky), "pulmonary venous congestion," "chronic passive congestion," and others, are used sometimes with gradual distinctions, sometimes interchangeably It appears to be useful, however, to distinguish the *overfilling of vessels*, arteries and veins, *without "leakage" of fluid* into the interstitial *spaces* and alveoli, from *the condition with* such escape of fluid, the *first condition* may properly be called *pulmonary vascular engorgement, or plethora,* the latter, *pulmonary congestion*. Both these conditions may occur acutely or they may be chronic. The first, vascular engorgement, may become "congestion," and this may deteriorate by sudden or gradual transition to full pulmonary edema This distinction between pulmonary vascular engorgement and pulmonary congestion is useful and should be attempted, even though transitional stages may occur and the distinction cannot be made, in every instance, on clinical and roentgenologic evidence

The causative factors do not generally influence amount and arrangement of edema fluid in such a gross morphologic way as to become distinguishable on the roentgenogram, though certain peculiarities occur in mitral stenosis, glomerulonephritis, the nephrotic syndrome, cor pulmonale of high resistance type, and marked emphysema Three factors, however, appear to influence the location of extravasated transudate and its roentgenologic appearance. (1) anatomical differences of the central and peripheral portions of the lung, (2) differences of the ventilatory excursion of the lung, and (3) the force of gravity. The first two factors will be discussed in connection with acute pulmonary edema. The third, gravity, influences the distribution of blood and tissue fluid even in the systemic circulation. Its effect is greater upon the pulmonary circulation with its low arterial and venous pressures. Not only the venous drainage, but also the lymph drainage of the lower and posterior portions of the lung occur against the influence of gravity In addition, the self-cleansing of the bronchial tree is easily interfered with in those dependent portions, adding obstructive atelectasis and drowning. All these are more marked in the presence of impaired ventilatory excursion. "Hypostasis" of old, obviously comprising all these disturbances, expresses the clinical fact that the dependent portions of the lung are preferentially affected by disturbances of the circulatory and ventilatory systems

PULMONARY VASCULAR ENGORGEMENT

Arterial hypertension in the pulmonary circulation, the result of increased resistance in emphysema, fibrosis, embolism, advanced mitral stenosis, or primary pulmonary hypertension, can produce demonstrable changes by dilatation of the larger branches of the pulmonary artery with or without accompanying dilatation of the pulmonary artery trunk. In this way, the hilar arteries become wider and plumper and also sometimes their main branches are widened. Often these arterial shadows show visible, i.e., increased (intrinsic) pulsations, as evidence of the greater systolic and pulse pressures. Large rounded shadows near the hilus, corresponding to dilated arteries in head-on view, show also distinct systolic expansive pulsations. All these vascular structures, though enlarged, are sharply defined, and the lung fields are clear or even abnormally translucent, as in emphysema or cor pulmonale

The preference of these changes for the dependent lung fields and an accompanying small pleural effusion, often revealed only by the thickened lesser interlobe, or a meniscus in the posterior costophrenic angle, may point in the right direction. One should be aware that borderline pulmonary congestion may be present without any obvious clinical signs and symptoms, even in the presence of normal circulation time

The amount of transudate in the lung may rapidly recede and completely disappear On the other hand, in chronic pulmonary congestion of cardiac origin, the strands of the increased lung markings may become thinner and regain their sharp definition Dense streaks and patches of consolidation, representing *fibrosis* and *hemosiderosis*, but also localized *transudate*, may now appear against the clear background of the rather dry lung of chronic *congestion*

PULMONARY CONGESTION IN AN EMPHYSEMATOUS LUNG

Emphysema counteracts the development and roentgenographic appearance of congestion and edema. In *bullous emphysema, the* total amount of *pulmonary tissue, including* the capillary-carrying alveolar walls, *is* considerably diminished, there are not enough *engorged* capillaries to provide for a hazy background, and engorgement, as far as it occurs, is overcompensated by preexisting *oligemia of* emphysema Furthermore, because *of the* scarcity of tissue there is *hardly* enough matrix for interstitial engorgement. *Therefore, in* marked emphysema, *pulmonary congestion* does not develop to any considerable degree, and stasis may easily escape *roentgenological detection If* the emphysema does not involve *the lung* in an even fashion, if only one lobe has large *bullae, or if* the emphysema involves only one lung, *the* congestive state may still be recognized in other portions On the other hand, the uneven or asymmetrical distribution may distract from the correct interpretation.

IRREGULAR ARRANGEMENT

While the roentgenographic diagnosis of pulmonary congestion and acute pulmonary edema in their *symmetrical* distribution is usually readily made, *transudate* may be distributed *in an* irregular fashion. Several causes for irregular distribution may be listed in addition to localized severe emphysema Edema accumulates when the lymph drainage cannot cope with the amount of fluid leaking from the capillaries. It has been shown by roentgen-pathological correlation and assumed from animal experiments that inflammatory lymphatic obstruction (Altschule, 1949) may be a contributory factor in the accumulation of transudate. In a lung where a previous pneumonic-pleuritic process has left a damaged lymph draining system, the drainage may still be sufficient under otherwise normal conditions In the case, however, of borderline cardiovascular decompensation, the injured area would accumulate edema, while the intact lung with its competent lymphatic drainage might still be kept dry Inhibited ventilatory excursion may also favor accumulation of transudate *in this* area Also, bronchial obstruction may accelerate transudation These factors, and probably also gravity, contribute to lobar, *unilateral, or* otherwise irregular distribution of pulmonary edema *In such a case,* with the loss of the "*normal distribution,*" *it is* sometimes impossible to discern from a single roentgenographic examination whether such irregular shadows are caused by congestion and edema, or by inflammatory infiltration

HEMOSIDEROSIS

In chronic pulmonary congestion, particu*larly in mitral* stenosis, considerable amounts of hemosiderin are frequently deposited *in the* lung The pigment is often arranged in nodular *fashion* causing a miliary picture on the roentgenogram. In rarer earlier stages, the iron pigment is sometimes deposited in and *along the greater interstices,* particularly the inter*lobular septa,* causing septal lines Occasionally, minute *(pea-sized)* irregular round shadows of calcific density are encountered. *preferentially in* the lungs of patients with mitral *stenosis. They* are more numerous in the lower lung fields and may be observed *to grow in size* over many years They are made up of well-organized bone and have been called *tuberous osteomas* (Salinger) Their occurrence does *not parallel* the degree of hemosiderosis, though *they too* seem to be a late product of blood extravasation, indicating *a not* yet fully understood response of *the lung* in mitral stenosis They should not be *mistaken for* in-

ill-defined, and cloudy; confluent shadows extend down to the lower lung fields, obscuring the contours of the cardiac silhouette (Fig. 18-5A). It becomes impossible to obtain "a *picture with good definition and contrast.*"

The increase in number and width of the vascular shadows is caused by their overfilling and widening. The general over-all haziness is due to *engorgement of the arterioles, venules, and capillaries.* In addition, the loss of clear contours and the over-all haziness are due to *increased moisture in the tissues,* and engorgement and distention of the perivascular, *peribronchial, septal, and subpleural lymph* vessels The hilar and perihilar lymph nodes are engorged with transudate (Zdansky). When the over-all congestion is limited, the combination of swollen blood vessels and lymphatics, and spotty interstitial and alveolar transudate, produce a *miliary appearance* remarkably similar to that of pneumoconiosis or even miliary tuberculosis. The patient whose x-ray films are seen in Fig. 18-5B had a long history of dust exposure and was treated for some time for pneumoconiosis before the mitral stenosis was recognized. After successful valvuloplasty, the fleck-like accumulations of edema, *surprisingly constant for a long time* and completely silent on auscultation, disappeared. Edema fluid causes rales only if it is located in alveoli, bronchioles, and bronchi; *interstitial moisture is silent to auscultation.* In other instances of prolonged stasis, interstitial fibrosis and hemosiderin deposits, appearing in a similar way, are of permanent nature, even in a dry lung and with good cardiac compensation.

CHRONIC PULMONARY EDEMA

There is sometimes a gradual transition from marked pulmonary congestion to a certain type *of pulmonary edema. The collections of transudate* in the parenchyma coalesce to larger areas of irregular, ill-defined accumulations of local edema, indistinguishable from pneumonic foci or from infarcts. This rather common type of pulmonary edema, superimposed upon or accompanied by signs of pulmonary vascular engorgement, is usually seen in congestive failure as it may occur in advanced mitral valve disease, hypertensive heart disease, myocardial insufficiency, and other disorders On the roentgenograms, the dense areas of maximal outflow of transudate are located about the hilar regions and lower lung fields and there is, in addition, coarse widening of the vascular shadows down to the diaphragm and the *peripheral lung fields. Isolated* small and large cloudy blotches of edematous infiltration may be seen anywhere else. However, they are rare in the upper lung fields Pleural effusion, preferentially on the right, is common.

The diagnostic difficulties are not exhausted with this systematic listing of the roentgen appearance of pulmonary vascular engorgement, congestion, and edema Clinical history and *present evidence of cardiovascular disease,* and roentgen evidence of abnormal size and shape of the heart and large vessels, should always lead to the consideration that pulmonary and pleural changes might be related to the cardiovascular condition. It is understood, however, that pulmonary congestion and edema may occur in patients whose hearts are of apparently normal size and shape Nevertheless, it is not uncommon that a heart of apparently normal size by standard measurement, may turn out to be moderately dilated, if compared with a previous chest film or with a later one, after recovery from congestive failure. It is some*times difficult to distinguish* dilated hilar arteries from enlarged lymph nodes or from a central consolidation, pneumonic or neoplastic. It is the shape and architecture of the shadow *mass,* and its expansile pulsation, not always distinguishable from transmitted pulsation, that mostly permit the identification. In addition to fluoroscopy, *laminography* may be helpful in proving the vascular nature of the mass and the freedom of the bronchi Bronchography, bronchoscopy, and, in rare instances, angiocardiography may be necessary to determine or exclude the vascular character of these shadows. The difficulties of the differential diag*nosis are still greater* with streaky, reticular, and small nodular or miliary formations in the peripheral lung fields: acute and chronic congestion, fibrosis, and hemosiderosis on the basis of chronic congestion; furthermore, the host of inflammatory, pneumoconiotic, hyperergic, and neoplastic changes has to be considered. Only careful weighing of all clinical evidence, including the observation of changes over short intervals, with or without treatment directed toward congestive failure, may reveal their congestive nature.

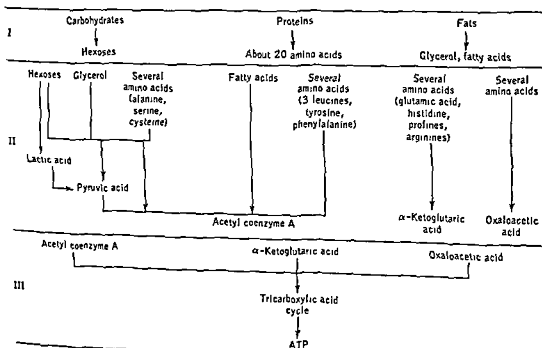
Special forms of heart failure



ROBERT M. P. HEGGLIN

HEART MUSCLE METABOLISM IN CARDIAC FAILURE

The term "heart muscle metabolism" refers to the chemical changes taking place in the myocardium during its muscle activity, i.e., during systole and diastole, these changes are required to produce sufficient energy for cardiac action at the needed time The heart muscle metabolism can be considered as twofold (see Part 2, Chaps. 1, 2, and 3) One can study (1) the chemical processes leading to the production of the most important phosphate compound, adenosinetriphosphate, ATP (production of energy), or (2) the processes taking place during contraction, a phase in which there is consumption of energy (utilization of energy).

From previous experimental results (mainly by Bing), it has been observed that, in the failing myocardium, disturbances occur in both phases, i.e., in production and utilization of

The Three Main Phases of Energy Production (after Krebs)

flammatory scars of tuberculosis or histoplasmosis

SEPTAL LINES

Horizontal linear shadows are often observed in the lower lateral lung fields. They are 1 to 3 cm long, about 1 mm wide, strictly horizontal, and spaced 0.5 to 1 cm apart. First described by Kerley (Kerley's lines B), they have been shown to be cast by interlobular septa, thickened by iron impregnation or edema (Fleischner and Reiner). In slightly advanced pulmonary hemosiderosis, iron pigment is occasionally arranged in and along interlobular septa, this fixed pigment lends itself to reliable roentgen-anatomical identification. More commonly, and in all instances of changing width and appearance, these septal lines are caused by *interstitial edema* in these septa, this is known to occur without appearance of edema in the alveoli and bronchioles (Parker and Weiss; Hayward). They do not correspond to individual engorged lymph vessels, as it was previously believed, though lymphatic stasis is a part of congestion and edema, and contributes to their roentgenographic appearance (Zdansky). The observation of these lines, their increase and decrease, presents a practical yardstick of the amount of abnormal moisture in the lung in many instances of beginning, subsiding, or borderline pulmonary congestion Though they correlate statistically with pulmonary arterial hypertension and more closely with capillary or venous hypertension, these septal lines are hardly indicative of any particular one of these hemodynamic irregularities beyond their general relation to the circulatory disturbances incident to pulmonary congestion and edema

PLEURAL TRANSUDATES

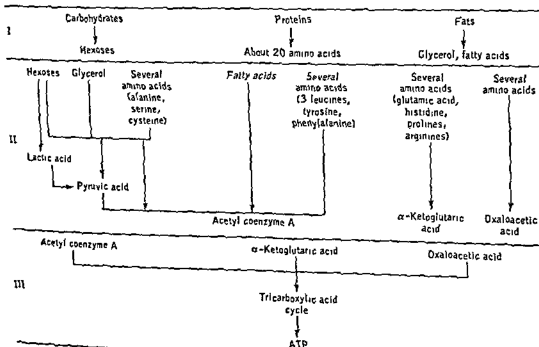
Pulmonary congestion and edema are often accompanied by *pleural effusion* Sometimes pleural effusion is the only apparent roentgenographic sign of congestion in the lesser circulation. This may be the case in glomerulonephritis with acute hypertension Small effusions are often arranged between the lung and diaphragm, and not visible as such in the usual anteroposterior view. A small fluid meniscus may fill the costophrenic angle, this is better seen in the oblique or lateral position A small effusion may also be seen on fluoroscopy when the patient bends over laterally to the examined side (*Hessen's maneuver*). Somewhat larger amounts of fluid surround the lung, the coat becoming thinner at higher levels This causes the usual shadows rising along the lateral chest wall with ill-defined upper contours. When the lung is congested, the presence and amount of pleural effusion often cannot be correctly assayed. A roentgenogram taken with a horizontal beam while the patient is in lateral decubitus will reveal the fluid arranged along the dependent chest wall. Unless fluid is encapsulated, this examination reveals fluid otherwise detained between lung and diaphragm, and permits a fairly exact estimate of its quantity. The observation of the interlobar fissures, particularly of the lesser "interlobe" (horizontal fissure), is quite helpful. Even small amounts of fluid, when otherwise invisible, become visible as thickening of the interlobe.

If the general pleural space is obliterated, transudate may be poured out into an interlobar pocket and cast a spherical or oblong shadow, usually easily recognized in its nature by its topographic relation to the interlobe, and by fine spicules extending into the fissure on either side. With improvement of the congestive failure, these shadows become narrower and disappear ("vanishing tumors").

Transudate developing in acute pulmonary edema or in the presence of ascites, such as in the nephrotic syndrome or constrictive pericarditis, has a great tendency to assemble exclusively between lung and diaphragm or in the cardiophrenic angle, causing misleading pictures of cardiomegaly, elevated diaphragm, or tumor On the left, the increased distance between the gastric air and the lung base readily suggests the presence of fluid in the diaphragmatic pleural space while, on the right, a "high diaphragm" and wavy shaking of the "diaphragm" seen on fluoroscopy raise a similar suspicion. *With a film* exposed while the patient is in the lateral decubitus, the diagnosis is readily established

9

Special forms of heart failure



ROBERT M. P. HEGGLIN

HEART MUSCLE METABOLISM IN CARDIAC FAILURE

The term "heart muscle metabolism" refers to the chemical changes taking place in the myocardium during its muscle activity, i.e., during systole and diastole, these changes are required to produce sufficient energy for cardiac action at the needed time. The heart muscle metabolism can be considered as twofold (*see* Part 2, *Chaps.* 1, 2, and 3) One can study (1) the chemical processes leading to the production of the most important phosphate compound, adenosinetriphosphate, ATP (production of energy), or (2) the processes taking place during contraction, a phase in which there is consumption of energy (utilization of energy).

From previous experimental results (mainly by Bing), it has been observed that, in the failing myocardium, disturbances occur in both phases, i.e., in production and utilization of

The Three Main Phases of Energy Production (after Krebs)

energy. Different forms of heart failure may take place according to the phase of metabolism which becomes abnormal. Cardiac metabolic studies try to correlate the symptoms of myocardial insufficiency with their causes, as this has been done with other clinical syndromes.

In *hypoxia*, ATP cannot be sufficiently built up. A decreased supply of oxygen to the heart muscle due to poor vascularization is an important cause of long-lasting cardiac insufficiency, especially if there is hypertrophy of the left ventricle. In *localized hypoxia* (coronary sclerosis) the parts of the heart muscle which are not involved are sufficiently supplied with oxygen. Actually, such a deficiency of oxygen as would cause insufficient production of energy is rare.

THE METABOLIC DISTURBANCES OF CARDIAC FAILURE

Theoretically, there are many possible causes for the disturbances of energy production or energy utilization. Though much progress has been made, knowledge concerning clinical forms of cardiac failure is still far from clear. The disturbance may consist of (1) abnormal synthesis of ATP due to disturbance of oxidation, lack of enzymes, or inhibition of enzyme activity (*disturbance of energy production*), or (2) abnormal synthesis of actomyosin, ionic imbalance, or changes in membrane permeability (*disturbance of energy utilization*).

The task of the future will be to identify the disturbance of myocardial metabolism present in any particular form of cardiac insufficiency and to correlate biochemical data with the clinical signs.

Disturbance of Energy Production. The simplest example is that of an extreme anoxemia (asphyxia). Complete blocking of the oxidative processes completely prevents the synthesis of ATP. Accordingly, the amount of ATP decreases in progressive total anoxemia (Schumann). After several minutes of anoxemia, the content of ATP in cardiac muscle is completely exhausted. The synthesis of ATP anaerobically through glycogenolysis is not sufficient to cope with the demand Clinically, this type of heart failure corresponds only to *an acute hypoxia*

Chronic hypoxia of the whole myocardium is clinically rare This would require extremely reduced oxygen tension in the blood, sluggish blood flow through the coronaries, or an increased oxygen demand by the tissues *Hemorrhagic shock* offers an example of disturbance of the production of energy by decreased oxygen consumption.

By means of catheterization of the coronary sinus, Bing showed that, in hemorrhagic shock (both in the oligemic and the normal phase), oxygen consumption is considerably reduced This is supposed to be caused by decreased coronary flow, since the oxygen intake was found unchanged. On the other hand, pyruvic acid utilization diminished, apparently due to the destruction of the cocarboxylase under anaerobic conditions, while lactic acid utilization was not impaired.

Animal experiments proved that decrease in oxygen consumption may also occur in extensive infarcts (Bing). Experimentally, coronary occlusion is not identical with myocardial infarction and is undoubtedly more extensive, as proved by the fact that the fall of blood pressure in Bing's experiments is 50 per cent greater than in clinical conditions In Bing's experiments, oxygen consumption decreased immediately after occlusion. In about half of the experiments, glucose and pyruvic and lactic acids were no longer taken up by the heart muscle, so that they appeared in increased amounts in the venous blood, while potassium and the inorganic phosphate were increased. These metabolic disturbances were transient and could be observed only immediately after the occlusion.

These metabolic processes are basically similar to those found in experimental ventricular fibrillation Lactic acid is found in large quantity in the coronary venous blood, indicating an extremely severe hypoxemic disturbance. According to the degree of hypoxemia, the pyruvic and lactic acid metabolism are differently influenced. In the most severe forms, lactic acid is formed through glycogenolysis (high level in the blood of the coronary sinus); in less severe cases, only the breakdown through cocarboxylase is diminished, due to destruction under anaerobic conditions (medium levels in the coronary venous blood).

In *beriberi heart*, synthesis of ATP is impaired because of the deficiency of thiamine which cannot be phosphorylated to cocarboxylase As there is not enough cocarboxylase, pyruvic acid cannot be utilized and broken

down by the citric acid cycle Therefore, pyruvic and lactic acid appear in the blood stream in increased quantities.

In *diabetes mellitus*, cardiac metabolism is typically changed Glucose utilization is diminished regardless of the high level of blood sugar. Also lactic and pyruvic acid utilization are decreased in the heart muscle, especially the former (Ungar et al). An impaired phosphorylation of thiamine to cocarboxylase is suspected (Foa et al , Siliprandi). On the other hand, the utilization of ketone bodies is increased (from 5 to 9 8 per cent, Bing). In human diabetes, utilization of fatty acids is especially increased Apparently fatty acids are stored in the heart muscle. Bing states that, in the diabetic heart, "there is a disturbance of energy production without diminished cardiac strength" in spite of the above-mentioned changes in myocardial metabolism It is difficult to separate clinically heart failure caused by diabetes from that due to the frequently associated coronary lesions On the other hand, in a diabetic patient, there also are ECG changes in the absence of failure (Q-T-U changes) which are more pronounced in the energeticodynamic type of failure and become more severe if coma supervenes

Disturbances of Utilization of Energy. The cardiac metabolism of congestive failure has been studied for a long time, though only in heart-lung preparations, by physiologists and experimental pathologists This experimental setup reproduces only approximately the conditions of slowly developing heart failure, and the conclusions reached cannot be used for clinical applications.

INVESTIGATIONS ON OXYGEN CONSUMPTION OF THE FAILING MYOCARDIUM The Starling law, founded on isolated heart studies, has dominated the clinical field for a long time According to this law, the oxygen consumption of an isolated heart under constant chemical conditions and constant temperature is determined by the diastolic volume, and thus by the initial length of the muscle fibers Since this length is increased in the failing heart, it was generally assumed that an increased oxygen consumption occurred in clinical cardiac insufficiency Using the catheterization of the coronary sinus (a method which allows a comparison of the coronary venous and arterial bloods and thus offers a direct picture of cardiac muscle metabolism), Goodale found that oxygen consumption of the failing heart increased somewhat per unit of weight. However, Bing did not find any changes Bing and Lorber explain this difference between the acutely failing isolated heart and the gradually decompensating myocardium of human beings by the fact that the volume-energy correlation of the myocardial fibers differs from that of the normal heart The fact that the decompensated heart under stress responds with an increased oxygen consumption supports this assumption It is questionable whether oxygen consumption can be correlated to the weight of the heart muscle because, in hypertrophied hearts, more or less extensive foci of fibrosis simulate a diminished oxygen consumption (naturally these foci do not contract and use little oxygen) while the insufficient fibers utilize more oxygen At any rate, the oxygen consumption of the failing heart is not decreased, as could be expected by virtue of impaired energy production

THE ENERGY-RICH PHOSPHATES IN INSUFFICIENT HEART MUSCLE. The total ATP content has been investigated in decompensated hearts but the results were not conclusive In an isolated insufficient heart, the ATP content was not changed (Wollenberger), in severe intoxication, it was found elevated On the other hand, the energy-rich phosphate compounds were determined in hearts of people who died in heart failure. The great majority of authors found a significant decrease in ATP as compared to the normal heart (Cowan, Herrmann, Linegar et al.). These results are to be interpreted cautiously since ATP is broken down very rapidly post-mortem, and it is impossible to know what occurs in every case before death Hypoxia, at any rate, causes a rapid and extensive decrease of ATP.

UPTAKE OF BASIC SUBSTANCES BY THE INSUFFICIENT HEART MUSCLE In eight cases of cardiac failure, Bing found that there is no statistically significant difference in the uptake by the cardiac muscle of glucose, pyruvic acid, lactic acid, amino acids, and ketone bodies.

INTERPRETATION OF METABOLIC DETERMINATIONS IN CONGESTIVE HEART FAILURE No significant metabolic changes have been found in

human hearts with evidence of congestive failure, in regard to either consumption or uptake of basic substances. As the uptake of these substances is not diminished, it has been concluded that, in congestive failure, *the disturbance depends upon the utilization of energy and not its production.* Bing considers this disturbance to be in the contractile proteins of heart muscle. However, in congestive heart failure, the myocardial fibers do not work under normal conditions. The requirements are always increased, either in order to overcome an increased arterial pressure, to compensate for valvular lesions, or to compensate for decrease of functioning muscle fibers (myocardial infarction, myocardial fibrosis, or myocarditis). This means that the disturbance in heart failure is not always in the proteins, but is due to an overloading of the cardiac fibers which goes beyond the level of good performance so that there are increased energy requirements during normal energy production. Therefore, the problem has to be viewed not as one of disturbed energy consumption, but as one dealing with more than physiological efficiency This problem must be considered, not as one of total cardiac activity (which is diminished in cardiac failure), but as one based on the work efficiency of the individual heart fibers, a parameter which cannot be figured out in individual cases Although, in congestive failure, the total cardiac activity is decreased, the activity of individual, still-functioning fibers may well be increased It has yet to be determined whether, in congestive failure, *additional factors are involved* which affect the myocardium and diminish the contraction (particularly hormonal and neurovegetative factors, as postulated by Raab). Up to now, no enzymatic influence is known which may cause heart failure, however, ATPase activity is influenced by electrolytes, and some electrolytic effect may be explained by altered ATPase activity

ELECTROLYTES Since the work of Szent-Gyorgyi et al, the influence of electrolytes upon the strength of cardiac contraction has been well known Not enough investigation has been *done on the effect of magnesium,* which is regarded as an antagonist of *calcium* A high blood level of calcium induces ECG changes but has no hemodynamic effect. In hypocalcemia, there is an initial lengthening of ejection time. If there is more marked effect, the ejection time can be considerably abbreviated and it must be assumed that the strength of contraction is diminished in calcium deficiency

Potassium influences contraction strength In the frog heart, the optimal potassium concentration is 4.8 moles Higher or lower concentrations diminish contractility. This can be explained as follows: at rest, the intracellular potassium prevents the union of actomyosin and ATP and the onset of contraction. During excitation, potassium diffuses through the membrane and contraction can take place *The strength of contraction is decisively influenced* by the concentration of potassium within the cells. By a gradual increase in potassium, the tension developed can be decreased in a graded fashion (Szent-Gyorgyi). Clinically, higher or lower levels of potassium lead to an energetico-dynamic type of cardiac failure which is characterized by a *shorter ejection time* accompanied by an early 2d sound The *early 2d sound* indicates weak contraction of the heart muscle, since the ventricular pressure is no longer able to overcome the aortic pressure for a sufficient length of time. Experimentally, little (and clinically, nothing) is known about the influence of the membranes on the strength of contraction Experimentally, Hajdu found certain relations between membrane potential, potassium, and the promptness of contraction; with high membrane-potentials, potassium has to decrease more before the onset of contraction. He postulates that, in infections, there is a membrane damage.

Membrane influences may also be considered the cause of diminished strength of contraction after complete denervation (experimental) and following nervous and hormonal influences in clinical cases (Raab).

THE INFLUENCE OF DIGITALIS ON MYOCARDIAL METABOLISM In spite of extensive investigations, the mode of action of digitalis has not yet been solved. Probably a multiple mechanism is involved Increased breakdown of energy-rich phosphates, influence upon the viscosity of contractile proteins, acceleration of polymerization of actin, and the subsequent increase of contractility of certain ATP-actomyosin preparations, influence the active ionic transport at the cell membrane in regard to inhibition of potassium (Rothlin and Taeschler).

TABLE 18-1 CAUSES OF CARDIAC INSUFFICIENCY

Cause	*Clinical condition*
Impairment of energy production:	
Due to lack of oxygen	Suffocation Hemorrhagic shock Severe coronary occlusion
Due to lack of enzymes	Beriberi
Due to insufficient substrate utilization	Diabetes mellitus
Insufficient energy utilization because of disturbance of:	
Contractile proteins	
Secondary to overload	Congestive heart failure
Primary	Myocardosis (example, hemochromatosis)
Altered ionic activities, chiefly potassium	Energeticodynamic, infectious, toxic
Altered membranes	Autonomic heart failure

VARIOUS FORMS OF CARDIAC INSUFFICIENCY

Theoretically, *heart failure* is mentioned whenever the myocardium is unable to deliver a certain output and to increase it if necessary Practically, in all cases the end-diastolic pressure is increased In a *hemodynamic type of failure*, the cause, in the majority of cases, lies in *abnormal requirements* of the heart muscle (increased pressure in the lesser or greater circulation, valvular damage, and disability of certain areas of heart muscle with resulting additional burden upon the remaining undamaged parts), and, more seldom, in a *lesion of the muscle fibers* themselves (so-called myocardosis in general)

The *pathogenesis* of hemodynamic cardiac insufficiency has been extensively studied during the last few years *Clinically* the effects of the cardiac failure are found more in the periphery than in the heart itself Except for the occasionally observed changes of tension, systole is clinically not shortened, even in the most severe cardiac insufficiency (hemodynamic), the rise of ventricular pressure is sustained for a sufficiently long period of time By recording simultaneous ECG and phonocardiograms, one can note that normally the 2d sound falls at the end of T wave This is different from the results of experimental work, where during increasing load one can observe, first a prolongation, then a marked abbreviation of ejection (Fig 18-6) Clinically, this abbreviation has been observed only in extreme cases, e g, in the terminal stage of hypertensive heart disease, while prolongation is frequently observed in the early stages of hypertension This marked discrepancy between the experimental and clinical observations of the insufficient myocardium has not been studied much until recently In certain clinical observations, this abbreviation of ejection was proved by a premature occurrence of the 2d sound in comparison with the end of T, even though there is a shorter Q-T interval. This can be observed in terminal stages of suffocation. Much more frequently, there is an abbreviated ejection and a prolongation of the Q-T segment (as it was believed to be in the past) or a T-U fusion (according to present knowl-

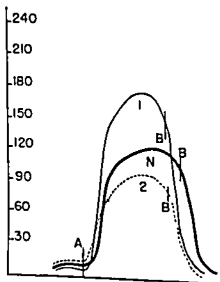


Fig 18-6 Curves representing the ventricular pressure and duration of systole A-B under various conditions N, normal curve; 1, curve after epinephrine, 2, weakness of contraction after chloral hydrate (notice the shortened systole A-B) (After Wiggers. *Circulatory Dynamics*. Grune & Stratton, 1952.)

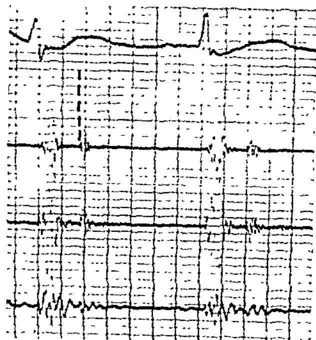

Fig. 18-7. Energeticodynamic cardiac insufficiency with hypopotassemia in diabetic coma. Sixty-five-year-old woman Potassium: 2.13 mEq/L. Blood pressure: 100/60 mm Hg. The mechanical systole is shortened by 0 09 sec as compared to normal.

edge). This then reveals changes, not only of the mechanical manifestations (2d sound) but also of the electrical phenomena (T-U fusion wave) (Fig 18-7) *This abbreviation of the ejection time should be considered as a manifestation of a decreasing contractility of the myocardial fibers because the heart muscle has not sufficient time to overcome the aortic pressure.* The changes of the ECG suggest disturbances in the metabolism of the heart muscle. The simultaneous appearance of *electrocardiographic metabolic disturbances* (T-U fusion wave = *energetic insufficiency*) explains the term *energeticodynamic insufficiency* With the exception of total anoxia (clinically rare), a premature 2d tone is always associated with corresponding electrocardiographic changes, while the ECG changes can be observed even without dynamic insufficiency, apparently, the metabolic disturbances are sometimes not severe enough to cause a marked weakness of the muscle. In such instances, there is an energetic (but not yet a dynamic) insufficiency This association of the typical electrocardiographic and hemodynamic alterations indicates an intimate connection

In most cases, there are disturbances of the electrolyte balance Potassium deficiency, and less frequently *hyperpotassemia,* are the most frequent findings. It is assumed that the electrolytes interfere with the actomyosin-ATP reaction (determining the strength of contraction). However, the degree of disturbance is not proportional to the degree of hypopotassemia. The dynamic disturbances are most severe (premature 2d sound) when hypopotassemia is combined with other severe disturbances in metabolism. *Hypochloremia* sometimes seems to be involved. In other conditions, especially in infectious or toxic conditions, the cause cannot be understood. It is conceivable that there is an influence upon the permeability of membranes regulating the exchanges of ions. Examples might be found in diabetic coma; hepatic coma; severe, prolonged diarrhea, prolonged vomiting; meningeal hemorrhage; liver cirrhosis; nephritis; severe toxic-infectious conditions with myocarditis (diphtheria, poliomyelitis), pneumonia. In rheumatic myocarditis, a prolongation of Q-T is often observed but not a premature 2d sound.

Clinical Manifestations. The characteristic electrocardiographic - phonocardiographic changes are necessary for a diagnosis *When the 2d tone is not synchronous with the end of the T wave,* there is good evidence that such a disturbance is present Normally, there is not more than 0.02 sec between the end of T and the beginning of the 2d tone. For practical purposes, it is not important to know if a U wave is hidden in the ending of the T wave The interval Q–2d sound is determined according to a formula (Hegglin and Holzmann) valid for the normal Q-T interval

$$0.39\sqrt{RR} \pm 0.04 \text{ sec}$$

Absolute abbreviations below the average value of −0.04 sec are rare. Average values of −0.02 sec can already be considered as pathological As the range of values (±0 04 sec) is large, serial examinations are of great importance (Figs. 18-8 and 18-9).

The diagnosis can be, however, *attempted* by using other clinical data. By means of *auscultation,* a trained ear can distinguish the premature 2d tone. The interval between the 1st and the 2d tone then becomes very short, something that old practitioners considered as an ominous prognostic sign. The *2d tone can* become soft. The *pulse* is small. The rate varies. there were cases with severe tachycardia

while others had a normal rate or even bradycardia The *blood pressure* is usually low, but not to such an extent that one can speak of collapse This syndrome, on the other hand, can be observed even in cases of arterial hypertension.

Congestion and *edema* are usually not observed (crepitant rales are occasionally present over the pulmonary bases). The *venous pressure* is not elevated *Circulation times* are abbreviated and become normal after improvement of the pathological condition The *circulatory volume* is decreased and *cardiac output* is also decreased There is nothing known about the intracardiac pressure conditions as no cardiac catheterization has been done in such cases

The prognosis depends upon the underlying disease The cardiac disturbance is reversible by adequate therapy (Fig 18-8). A very premature 2d sound, however, is significant of a poor prognosis

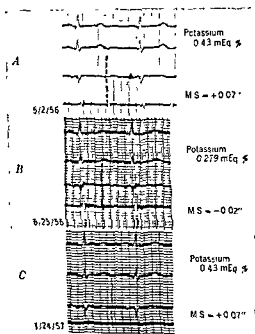

Fig 18 8 Changing length of the mechanical duration of systole in serial examinations (case of interstitial nephritis) A, Normal behavior B T-U-fusion wave as an expression of disturbance of myocardial metabolism (hypopotassemia potassium = 2 79 mEq/L), energetic insufficiency The mechanical systole is shortened only insignificantly by 0 02 sec C, Normalization of the serum potassium and of the electrocardiogram.

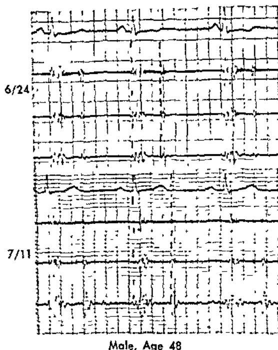

Fig. 18-9. Development of a typical cardiac insufficiency of the energetic-dynamic type in a patient with acute myocarditis and no changes in electrolytes Forty-eight-year-old man The mechanical systole, shortened by 0 08 sec on 6 24, reached the average value on 7/11. During a rate of 75 per minute, the interval Q–2d sound changed from 0 25 to 0 33 sec

I

Causes and clinical picture of paroxysmal pulmonary edema

ALDO A. LUISADA

Paroxysmal pulmonary edema, first described two centuries ago, is still a subject of great interest to clinicians and physiologists At present, acute pulmonary edema is considered by most clinicians to be a manifestation of failure of the left ventricle, the clinical symptoms being due to back-pressure into the blood vessels of the lung. This concept was originally based on the experimental studies of Welch (1878) who reported the development of pulmonary edema in rabbits as a result of interference with the function of the left ventricle. Indeed, the back-pressure concept is not limited solely to acute pulmonary edema but has been extended to the respiratory manifestations of chronic congestive failure as well (Harrison) As experimental and clinical observations on pulmonary edema have accumulated, it has become clear that the validity of the "back-pressure" or "left ventricular failure" theory of acute pulmonary edema can no longer be considered established and that it should be considered, at best, incomplete

As defined by Laennec, "Edema of the lung is the infiltration of serum into the substance of this organ, in such degree as evidently to diminish its permeability to the air, in respiration" While edema of the lungs is initially similar to edema of other organs, the structures surrounding the capillaries are so thin that an immediate outpouring of fluid into the alveolar cavities occurs. In this respect, pulmonary "edema" is followed by pulmonary "exudation" To a more limited extent, fluid also appears in the pleural cavities.

The term "pulmonary edema" carries with it different associations to different specialists to the pediatrician, acute glomerulonephritis or rheumatic carditis; to the surgeon, thoracic or abdominal intervention, to the neurologist, cerebrovascular accident or trauma to the skull, to the cardiologist, hypertension, coronary occlusion, or mitral stenosis.

HISTORY

The history of lung edema is long. Although nearly two centuries have elapsed since the first clinical description, the first experimental researches were performed nearly 100 years ago

The multiplicity of the causes which give rise to attacks of lung edema and the different theories attempting to explain it call attention to the fact that it is one of the most interesting, although still obscure, acute syndromes.

A brief list of the chief studies on the subject will be of some interest.

1752 Maloet, clinical description
1753: Barrère and Albertini, clinical study
1760–1770 van Swieten, Sir Percival Scott; clinical studies.
1819 Laennec, inflammatory lung edema, lung edema in patients with cardiac diseases.

1834· Andral, acute and chronic lung edema

1836 Legendre, inflammatory lung edema during scarlet fever, acute lung edema in patients with nephritis.

1850–1860 Devay, Rilliez, and Barthez, complete description of the clinical picture

1850–1860. Virchow, research on lung edema following fat embolism

1850–1860. Cohnheim and Lichtheim, research on lung edema after intravenous salt solution infusion

1869. Peter, lung edema in pregnant women

1873: Terrillon, lung edema following thoracentesis.

1873 Souin de la Savinière, lung edema during pneumonia.

1877: von Frey, experimental researches on cutting of vagus nerves

1878 Welch, lung edema of the rabbit either by ligature of the aorta or by compression of the left ventricle

1878. S Mayer, lung edema of the rabbit by brain ischemia.

1879 Huchard, clinical study on the relationship between lung edema and aortic lesions.

1880–1896 von Basch, Loewit, Grossmann, Winkler, experimental research on toxic lung edema

1888 Sahli, research on experimental edema by ligature of the aorta and by compression of the left ventricle in the dog.

1892 Alexandrow, experimental research on mechanical lung edema

1897 Huchard and Claude, experimental researches on lung edema caused by epinephrine.

1900. Sticker, clinical study on lung edema

1900 International meeting in Paris on lung edema (von Basch, Teissier, Huchard, Potain)

1901 Teissier and Guinard, experimental research on lung edema

1904 Meltzer, pathophysiology of pulmonary edema.

1906 Joreš, research on neurogenic lung edema.

1908–1912 Josué, Cavina, experimental lung edema caused by epinephrine

1909 Miller and Matthews, experimental lung edema

1912 Barringer, acute lung edema during pregnancy and labor

1910–1912 Lian and Vaquez, complete formation of the theory "lung edema is the result of left ventricular failure"

1913 Kotowschtschikow, research on mechanical and toxic lung edema of the rabbit and dog

1918–1927 Moutier, Antonini and Biancalani, acute lung edema caused by injury to the skull

1923–1933 Gallavardin, Sfloz and Frommel, Doumer, Hess, Schellong, acute lung edema in patients with mitral stenosis

1923–1926 Barry; Anrep and Bulatao; Lambert and Gremels, lung edema in heart-lung preparations

1928. Luisada, experimental research on epinephrine pulmonary edema and on the therapeutic value of narcotics and sedatives.

1929. Luisada, intravenous therapy of clinical pulmonary edema with morphine, chloral, and barbiturates

1929 Glass, Boggian, inhibition of epinephrine pulmonary edema by lesions of the brain or of the sympathetic system

1929 Antoniazzi, lung edema by ligature of the aorta, influence of nervous stimuli and of drugs in its prevention.

1930 Luisada, experimental lung edema caused by cerebral hypertension.

1930–1931. Frugoni (with Melli, Peserico, Luisada), acute lung edema. A report to the Italian Meeting of Internal Medicine, and a monograph

1929–1932 Zdansky, x-ray studies on pulmonary edema

1931–1933 Bsteh; Gernez and Marchandise, clinical studies on lung edema in neurological conditions

1932. Weiser, vagal pneumonia-pulmonary edema

1932 Luisada, criticism of the theory of isolated ventricular failures (monograph).

1931–1933 Hess, clinical studies of pulmonary edema after coronary occlusion

1933 Coelho and associates, lung edema by experimental lesions of the left ventricle on the dog.

1934 Reinhardt, experimental researches on lung edema with microscopic control

1934 S Wassermann, a monographic study on clinical lung edema.

1934 Brunn, luminal inhibition of experimental lung edema

1935 McGinn and White, acute cor pulmonale

1935 Cataldi, pulmonary edema by experimental lesions of the right ventricle

1934–1938 Cataldi, Rubino, studies on dynamic effects of the experimental lesions of either the right or the left ventricle, and of ligature of either coronary artery.

1932–1938 Hochrein and associates, the lung a blood depot, vasomotor changes of the lung vessels

1934–1939 Laubry and Cottet, Manunza, Astuni, Weissmann, lung edema in the diseases of the nervous system and after trauma to the skull.

1936 Moon and Morgan, experimental lung edema during shock

1937 Farber, lung edema by cutting of the vagus nerves.

1938. Barach, positive pressure in the treatment of pulmonary edema.

1939: Jarisch and associates, central lung edema by suboccipital injection of veratrin in animals.

1940–1944: Cournand and associates; Dexter and associates; changes of pulmonary pressures studied by catheterization

1944: Sarnoff et al., spinal anesthesia as treatment of pulmonary edema.

1945. Drinker, monograph on pulmonary edema.

1946· Luisada and Sarnoff, Paroxysmal pulmonary edema consequent to stimulation of cardiovascular receptors

1948: Daniel and Cate, the surgical "wet lung."

1949: Visscher et al., pulmonary edema in animals with increased cranial pressure.

1949: Koenig and Koenig, ammonium chloride pulmonary edema.

1949: Cameron et al., neurogenic pulmonary edema.

1950: McKay, edema of the lung in trauma to the skull. *Hypoglycemic pulmonary edema.*

1950: Luisada, antifoaming agents in experimental pulmonary edema.

CAUSATIVE FACTORS

Paroxysmal pulmonary edema can be encountered in a great variety of conditions, as shown by *necropsy findings* (Tables 18-2, 18-3). A list of the various conditions which may be associated with acute pulmonary edema is presented below. As a large number of clinical cases succumb without pulmonary edema, this disorder is not a "terminal" or "agonal" phenomenon.

A brief review of the most common causes of pulmonary edema in clinical cases follows.

Pulmonary Edema and Arterial Hypertension. This type of pulmonary edema was most common in the past, but is now seen less frequently, partly because of the development of more effective treatments, and partly because other types tend to predominate. *Chronic nephritis with uremia* is frequently accompanied by episodes of edema of the lungs, but sometimes moderate nitrogen retention is the only evidence of renal insufficiency, and there may be little or no *acidosis*. All other forms of hypertension, including essential hypertension and that of coarctation of the aorta, may present pulmonary edema. Patients with *malignant hypertension* have these paroxysmal attacks more commonly than others

Pulmonary Edema and Coronary Heart Disease. The observation that severe coronary occlusion is frequently accompanied by pulmonary edema has led to the belief that minor coronary episodes may also contribute to these attacks. However, no certain proof has been

Clinical Conditions Associated with Acute Pulmonary Edema

I Cardiovascular disease
- *A* Syphilitic heart disease (aortic insufficiency, aortitis; aortic aneurysm)
- *B* Rheumatic heart disease (acute rheumatic carditis; mitral insufficiency; mitral stenosis; aortic insufficiency; aortic stenosis)
- *C.* Coronary heart disease (severe, acute coronary occlusion; minor occlusion plus extensive ischemia or fibrosis of the myocardium)
- *D* [illegible] glomerulo- [illegible]
- *E.* [illegible] patent [illegible]
- *F* [illegible]
- *G* [illegible]
- *H* Congestive failure

II Diseases or lesions of the central nervous system
- *A* Trauma to the skull
- *B* [illegible] tumor)

[illegible]
- *A* Pneumonia, bronchopneumonia (especially influenzal)
- *B* Drowning, strangulation, asphyxia, respiratory obstruction (edema of the glottis, bronchial asthma, foreign bodies)
- *C* Inhalation of irritant or toxic gases (including those used in warfare), respiratory burns
- *D* Following rapid thoracentesis
- *E* Following trauma to the chest
- *F* Following lobectomy

IV Allergy
- *A* Angioneurotic edema, serum sickness, following injection of gold preparations; following inhalation of penicillin aerosol

V [illegible]

VI Surgical and obstetric cases
- *A* During pregnancy or after labor (especially, but not only, in cases with rheumatic heart disease, [illegible]
- *B* [illegible]
- *C* [illegible]

VII Toxic
- *A* Following use or overdose of thiourea derivatives, iodides, muscarine, eserine, Prostigmine, opium, methyl salicylate, acetic and butyric ether, phenylcarbamide

VIII Miscellaneous
- *A* Thyroid crises, beriberi, insulin shock, burns

presented, and the mechanism of production of the edema might be somewhat different from that in hypertensive patients *Cardiogenic shock* caused by coronary occlusion is more frequently associated with pulmonary edema than other types of shock Protracted forms of edema of the lungs are common in coronary heart patients

Pulmonary Edema and Cerebral Diseases. The occurrence of pulmonary edema in cases of meningitis, encephalitis, or brain tumor is relatively common, in children as well as in adults *Cerebrovascular attacks,* including hemorrhage, embolism or thrombosis, and subarachnoid hemorrhage, as well as trauma to the skull, are frequently followed by pulmonary edema Undoubtedly, coronary lesions and preexisting hypertension may be contributing factors in certain cases. However, in others, no evidence of such lesion or disorder can be demonstrated clinically following recovery, or at autopsy.

Manipulation of the Stellate Ganglia. Early in the history of sympathetic surgery for coronary heart disease, acute pulmonary edema was reported to occur during the course of manipulation of the stellate ganglia in about half of the cases (Jonnesco, Danielopolu) More recently, probably as a result of refinement of technique, this has become uncommon.

Pulmonary Edema and Pulmonary Heart Disease. Contrary to current opinion, this as-

sociation is far from rare. Pulmonary edema may follow *pulmonary embolism*. Occlusion of one stem of the pulmonary artery causes increased flow in the other, and this may favor high capillary pressure in one lung Even occlusion of smaller branches may cause diffuse, bilateral edema, a fact which has led to numerous speculations on the possibility of either diffuse reflexes acting on the pulmonary vessels or the liberation of substances increasing the permeability of the capillaries.

Acute pulmonary edema may develop even in *chronic cor pulmonale* with right ventricular hypertrophy and pulmonary hypertension. It should be kept in mind that chronic cor pulmonale (or pulmonary heart disease) is the result of a long-lasting, usually diffuse, lesion of the lungs.

Several forms should be differentiated:

1. The form due to *increased flow* plus vasoconstriction or minor arteriosclerotic lesions of the arterioles This form, called "hyperkinetic" by Wood, is typical of congenital shunts.

2. The form caused by *obstructive lesions of the pulmonary arterioles* (primary pulmonary arteriosclerosis, secondary arteriosclerosis of mitral stenosis, and syphilitic arteritis). This leads to pulmonary arterial hypertension and right ventricular strain while no impairment of the gas exchange between pulmonary capillaries and alveoli takes place. There is *no* decrease in oxygen saturation of the arterial blood and *no* polycythemia until the late stages.

3 The form caused by *obliterative lesions of the pulmonary parenchyma* (pulmonary emphysema, pulmonary fibrosis which may follow extensive pneumonia, bronchopneumonia, pulmonary tuberculosis, or bronchiectasis; diffuse but slowly growing cancer of the lungs, and multiple and repeated pulmonary infarctions) This leads to pulmonary hypertension through destruction of the capillaries and is followed by a decrease in the oxygen saturation of the arterial blood (hypoxia) and polycythemia.

4. The form caused by *impairment of respiration* due to kyphoscoliosis or other *deformity of the chest*. It may cause hypoxia

5. The form caused by an *arteriovenous shunt* due to one or more fistulas of the lung. The bypassing of the capillaries may cause hypoxia

For a long time, it was denied that edema of the pulmonary parenchyma might occur in chronic cor pulmonale because any obstruction of the small vessels, while increasing the pressure in the main pulmonary artery and the right ventricle, would also decrease the pressure in the capillaries, the most important site in regard to the formation of edema. However, as shown above, not all forms of chronic cor pulmonale are due to obstruction of capillary flow or destruction of capillaries. Moreover, it should be kept in mind that pulmonary fibrosis frequently predominates in certain areas of the lungs while other areas are intact. It is likely that vascular obstruction, or destruction of a number of portions of the vascular tree, favors pulmonary edema of the intact areas. It is *known that one-half of the pulmonary vessels* can carry the entire flow of the lesser circulation without any increase in pressure. However, this is obtained through distention of the normal vessels, which in itself predisposes to edema. Whenever an increase of venous return takes place in patients with such a distention, the already distended (normal) vessels are taxed beyond physiologic limits, and transudation is more likely to occur in them

Sudden pulmonary edema has been observed in patients with *deformity of the chest* ("pulmonocardiac failure" of Chapman et al). The importance of further lowering of oxygen saturation in such cases cannot be overemphasized *Hypoxia*, as first shown by Drinker, favors pulmonary edema, both through increase of permeability and through increase of pressure in the pulmonary capillaries

Whenever other causes of pulmonary edema are present, *this condition may* also develop in chronic cor pulmonale. This particularly applies to systemic hypertension and coronary heart disease.

Pulmonary Edema in Trauma to the Chest. This syndrome, called by surgeons "traumatic wet lung," has been the object of considerable speculation, and is of particular *interest* because it spreads from the damaged to the intact areas of the lungs.

Thoracentesis. Although the older literature contains references to pulmonary edema following thoracentesis, it is only occasionally seen now. It is likely that refinements in technique (slow decompression) are responsible for the disappearance of this complication

Drowning. The fluid found in the lungs of drowned persons and *animals* has a high protein content (Biondi; Melli; Farber, 1937b). This must result from the transudation of serum into the alveoli, i e., pulmonary edema

Uremia. Acute pulmonary edema is frequently observed during the course of chronic uremia It is especially common in patients who are receiving intravenous infusions of fluid, even at rates as low as 4 to 10 drops/min This is usually ascribed to failure of the left ventricle although positive evidence in that regard is lacking. Moreover, these patients show a predominant dilatation of the right atrium and ventricle. Blood dilution with decreased osmotic pressure of the plasma is likely to be another factor.

Allergy. The possibility of the occurrence of angioneurotic edema of the lungs cannot be ruled out. In a comprehensive statistical study of allergic patients, Frugoni saw no proved case of this disorder, although in many cases an allergic origin was claimed by various authors, in some instances rather convincingly (Sticker). If allergic pulmonary edema does occur, it is clear that there is nothing to suggest that left ventricular failure is implicated Constriction of pulmonary venules, typical in rodents, fairly well developed in carnivores, could be a factor in man.

Pulmonary Edema and Shock. Shock is frequently associated with pulmonary edema It is not known whether shock itself causes pulmonary edema or whether both shock and pulmonary edema result from a common cause Experimental *anaphylactic shock* is usually accompanied by pulmonary edema, as is the episode of *cardiogenic shock* in clinical cases As the former is primarily a vascular disorder while, in the latter, the low blood pressure is due to a cardiac disturbance, it is likely that an upset of the normal hydrostatic/osmotic balance of the capillaries is a factor whenever too severe and prolonged hypotension takes place

Thyroid Crises. Acute pulmonary edema may terminate the course of thyroid crises Its occurrence is usually explained on the basis of left ventricular failure due to increased cardiac output, hypertension, and impaired nutrition of the myocardium.

Beriberi. This disease frequently results in acute pulmonary edema. Since beriberi heart is usually considered due to right heart failure, it is evident that failure of the left ventricle cannot be implicated, neuritis of the vagus has been offered as a possible, though unconvincing, explanation for this type of pulmonary edema. Direct effect on the capillary wall is, of course, a possibility

Stimulation of Hollow Viscera. The older literature contains many instances of pulmonary edema associated with distention of some abdominal organ, usually the stomach. More recent cases are those of Hochrein (stomach) and Vigi (esophagus). These cases are hard to evaluate, either because of inadequate study or incompletely presented data, or because the patients were old persons with coronary sclerosis, valvular defects, or hypertension It is probable that rapid distention of a hollow viscus does not by itself cause pulmonary edema, though the importance of nervous reflexes is suggested. In rare instances, sudden emptying of a distended bladder in patients with prostatic obstruction may apparently result in the development of acute pulmonary edema (Frugoni) This phenomenon is difficult to evaluate, since often the patients in whom it occurs have marked coronary sclerosis, hypertension, or both.

Pregnancy. A number of authors during the last century stressed the relationship between pregnancy and pulmonary edema in some patients Since patients developing this complication have valvular heart disease or hypertension associated with toxemia, this type of pulmonary edema is best considered together with that due to heart disease. Increased blood volume is, however, an additional factor.

Pulmonary Edema in Mitral Stenosis. The occurrence of pulmonary edema in cases with a persistent block *before* the left ventricle contradicted the established theory attributing these episodes to acute left ventricular failure It is only in recent years that an adequate dynamic explanation has been found. Patients with mitral stenosis occasionally cough up large amounts of pure blood. This syndrome, called *"pulmonary apoplexy,"* is closely related to pulmonary edema, and has a similar, though not identical, mechanism.

Pulmonary Edema and Infections. Pulmonary edema and bacterial pneumonia may be closely interrelated because pneumonia may predispose to pulmonary edema (infectious pulmonary edema) and vice versa (infected pulmonary edema) Furthermore, either of these conditions may simulate the other. Many other febrile diseases may be complicated by pulmonary edema, partly through

sociation is far from rare. Pulmonary edema may follow *pulmonary embolism.* Occlusion of one stem of the pulmonary artery causes increased flow in the other, and this may favor high capillary pressure in one lung. Even occlusion of smaller branches may cause diffuse, bilateral edema, a fact which has led to numerous speculations on the possibility of either *diffuse reflexes acting on the pulmonary vessels* or the liberation of substances increasing the permeability of the capillaries.

Acute pulmonary edema may develop even in *chronic cor pulmonale* with right ventricular hypertrophy and pulmonary hypertension. It should be kept in mind that chronic cor pulmonale (or pulmonary heart disease) is the result of a long-lasting, usually diffuse, lesion of the lungs.

Several forms should be differentiated.

1. The form due to *increased flow* plus vasoconstriction or minor arteriosclerotic lesions of the arterioles This form, called "hyperkinetic" by Wood, is typical of congenital shunts.

2 The form caused by *obstructive lesions of the pulmonary arterioles* (primary pulmonary arteriosclerosis, secondary arteriosclerosis of mitral stenosis, and syphilitic arteritis) This leads to pulmonary arterial hypertension and right ventricular strain while no impairment of the gas exchange between pulmonary capillaries and alveoli takes place. There is *no* decrease in oxygen saturation of the arterial blood and *no* polycythemia until the *late stages*

3 The form caused by *obliterative lesions of the pulmonary parenchyma* (pulmonary emphysema; pulmonary fibrosis which may follow extensive pneumonia, bronchopneumonia, pulmonary tuberculosis, or bronchiectasis, diffuse but slowly growing cancer of the lungs, and multiple and repeated pulmonary infarctions) This leads to pulmonary hypertension through destruction of the capillaries and is followed by a decrease in the oxygen saturation of the arterial blood (hypoxia) and polycythemia.

4. The form caused by *impairment of respiration* due to kyphoscoliosis or other *deformity of the chest* It may cause hypoxia

5 The form caused by an *arteriovenous shunt* due to one or more fistulas of the lung The bypassing of the capillaries may cause hypoxia

For a long time, it was denied that edema of the pulmonary parenchyma might occur in chronic cor pulmonale because any obstruction of the small vessels, while increasing the pressure in the main pulmonary artery and the right ventricle, would also decrease the pressure in the capillaries, the most important site in regard to the formation of edema However, as shown above, not all forms of chronic cor pulmonale are due to obstruction of capillary flow or destruction of capillaries. Moreover, it should be kept in mind that pulmonary fibrosis frequently predominates in certain areas of the lungs while other areas are intact It is likely that vascular obstruction, or destruction of a number of portions of the vascular tree, favors pulmonary edema of the intact areas. It is known that one-half of the pulmonary vessels can carry the entire flow of the lesser circulation without any increase in pressure. However, this is obtained through distention of the normal vessels, which in itself predisposes to edema. Whenever an increase of venous return takes place in patients with such a distention, the already distended (normal) vessels are taxed beyond physiologic limits, and transudation is more likely to occur in them

Sudden pulmonary edema has been observed in patients with *deformity of the chest* ("pulmonocardiac failure" of Chapman et al.). The importance of further lowering of oxygen saturation in such cases cannot be overemphasized *Hypoxia*, as first shown by Drinker, favors pulmonary edema, both through increase of permeability and through increase of pressure in the pulmonary capillaries

Whenever other causes of pulmonary edema are present, this condition may also develop in chronic cor pulmonale. This particularly applies to systemic hypertension and coronary heart disease.

Pulmonary Edema in Trauma to the Chest. This syndrome, called by surgeons "traumatic wet lung," has been the object of considerable speculation, and is of particular interest because it spreads from the damaged to the intact areas of the lungs.

Thoracentesis. Although the older literature contains references to pulmonary edema following thoracentesis, it is only occasionally seen now. It is likely that refinements in technique (slow decompression) are responsible for the disappearance of this complication

Drowning. The fluid found in the lungs of drowned persons and animals has a high protein content (Biondi; Melli, Farber, 1937b). This must result from the transudation of serum into the alveoli, i e., pulmonary edema

repercussions of inflammatory lesions of the heart, lungs, or brain, and partly through possible overload of the circulation caused by therapeutic intravenous infusions. Unexplained edema of the lungs may also develop during the chill phase of a febrile reaction. Acute infectious pulmonary edema was discussed (in this and other diseases) by Logre, and more recently, by Robin and Thomas.

Pneumonitis. Viral pneumonitis, especially *influenzal*, may cause pulmonary edema, even in young patients in whom there is no evidence of heart disease. During epidemics of influenza, acute pulmonary edema is a not infrequent cause of death.

THE CLINICAL EPISODE

An attack of pulmonary edema may occur at any time of the day or night. Precordial oppression or pain, restlessness, weakness, and dry nonproductive cough, may precede the attack If this occurs at night, a nightmare frequently precedes the paroxysm. Respiration becomes difficult and labored, and is usually accelerated The patient is obliged to sit up, and may lean forward Within a few minutes, gurgling sounds can be heard, and the patient repeatedly emits a white, yellowish, or pink *frothy sputum*. This may vary from a few bubbles to enormous amounts (as much as 2,000 to 3,000 ml of foam within 1 to 2 hr). Cold, clammy extremities, paroxysms of suffocation, and vomiting may occur.

In most cases connected with coronary occlusion, pulmonary embolism, or allergic shock, the pulse is rapid and small (and may be irregular), and the blood pressure drops gradually, sometimes reaching shock level Some cases with a rheumatic mitral lesion also experience a drop in blood pressure.

Other cases, and particularly those occurring in hypertensive or syphilitic heart disease, and those connected with a cerebrovascular attack, present a full pulse and a blood pressure which is high, and sometimes higher than before the attack.

Physical examination reveals a high, tympanic percussion sound over the lung fields and innumerable moist rales over the entire chest, from the soft rales arising in the small bronchi to the gurgling sounds created by the foam in the trachea.

The *temperature* is usually normal during the attack, except in inflammatory edema, but may rise soon afterward because of reabsorption of altered proteins from the lungs.

The *sputum* has a chemical composition similar to the fluid of angioneurotic edema or allergic coryza and to the inflammatory effusions of large serosal cavities. This is true, not only of clinical episodes, but also of experimentally induced attacks.

Catheterization of the right heart in clinical cases has revealed that pulmonary arterial pressure is severely increased, and that pulmonary artery wedge pressure may reach from 32 to 45 mm Hg during the attack (Lenègre and Scébat).

VARIETIES

Extreme difference can occur in the clinical picture of pulmonary edema according to the severity, extension, duration, and clinical picture.

Extension. Pulmonary edema is usually bilateral and, contrary to common belief, it usually starts in the hilar regions, then diffusing to the rest of the lungs. Certain forms of moderate severity may not involve all the parenchyma of both lungs. *Unilateral pulmonary edema* is possible. It is usually favored by decubitus, infection of one lung, or neurological phenomena The author has observed one case where it was connected with a small abscess of one lung plus a contralateral cerebral embolism (autopsy confirmed these facts).

Other cases were described by Stricker and by Teissier.

Duration. Certain episodes are *fulminating*, so that the occurrence of edema of the lung is only an autopsy finding Most serious cases last for 20 min to 2 to 3 hr and thus give ample time for treatment. These are the *acute cases* A special variety has been called *protracted edema* (Goldmann and Luisada) It occurs following either a myocardial infarct or a cerebrovascular accident. It starts as an acute form and then continues for 6 to 24 hr, and even longer. *Chronic pulmonary edema* obviously is not described here.

Severity. The severity of an attack is not always proportional to its duration Severe episodes may disappear after 15 to 30 min while moderate episodes may be prolonged and last several hours.

Clinical Picture. One symptom or sign may predominate. Precordial pain or oppression, cough, asphyxia (bronchoplegic form), un-

consciousness, abundance of expectoration, or hemorrhagic sputum, can predominate. Precordial pain is typical of myocardial infarction; loss of consciousness is common in cerebral episodes; bloody sputum is typical of mitral stenosis.

Wheezing respiration is uncommon but may occur Then, expectoration is usually moderate while dyspnea is extremely severe.

THE TWO MAIN TYPES OF PULMONARY EDEMA

While different signs have led to the recognition of various clinical pictures of pulmonary edema, two groups deserve distinction because of the different effect that treatment exerts on the clinical picture and on the final course.

Patients of the *first group*, who seem to be the most numerous, present evidence of increased blood pressure, rapid circulation, increased cardiac output, and extreme rise in pulmonary arterial pressure This group includes patients with hypertensive heart disease; patients with syphilitic or rheumatic heart disease and aortic insufficiency, some instances of cerebrovascular accidents, mitral insufficiency, or minor coronary episodes, and patients treated with overabundant venous infusions or transfusions. It is apparent that any method which succeeds in decreasing venous return to the right heart will be helpful in this type of edema

Patients of the *second group*, less numerous but tending to increase, present either no change or a drop in blood pressure, decreased cardiac output, and a more moderate rise in pulmonary arterial pressure (some cases may even have a normal pulmonary arterial pressure) This group includes patients with massive myocardial infarct, some instances of severe mitral or aortic block, some patients who have inhaled toxic gases, some instances of cerebrovascular accident, and some patients with toxic, rheumatic, or bacterial myocarditis While a reduction in venous return may be useful in these patients, it also carries with it the danger of precipitating shock

CARDIOVASCULAR DYNAMICS IN CLINICAL CASES

It is difficult to obtain data on the cardiovascular dynamics during acute pulmonary edema. The attacks are frequently of short duration or, if sufficiently prolonged to permit accurate observations, make the patient extremely uncomfortable and even desperately ill. Nevertheless, valuable data can be obtained from observations made in milder forms of paroxysmal cardiac dyspnea, which are closely related to the syndrome of acute pulmonary edema itself, or from patients who experienced pulmonary edema during cardiac catheterization. The latter has been the object of a study by Lenègre and Scébat.

Measurements of *pulse rate* and *blood pressure* are easily obtained during attacks of pulmonary edema or paroxysmal dyspnea. In most instances, both are elevated during the attack but blood pressure may be low or follow a slowly decreasing course.

Venous pressure has been measured by Weiss and Robb and by Altschule in patients with paroxysmal dyspnea, and a considerable increase was found in some. Altschule suggested that this was due to a rise in intrapleural pressure associated with loss of elasticity and distensibility of the lungs and with increased respiratory efforts. Altschule also advanced the hypothesis that this phenomenon might be important in terminating some attacks, the rise in intrapleural pressure impounding blood in the peripheral veins in a manner similar to tourniquets on the extremities In shock associated with pulmonary edema, the veins are collapsed and the venous pressure is very low.

Studies of the *vital capacity* by Weiss and Robb revealed a considerable decrease during attacks of paroxysmal dyspnea The pulmonary circulation time is also prolonged and the arterial oxygen saturation decreases. These observations explain the dyspnea observed during the attacks.

Measurements of the *cardiac output* during paroxysmal dyspnea are few Eppinger and coworkers made such a study but the method used is now discredited. Lauter, using the Fick principle and cardiac puncture, found (in three cases) a diminished blood flow through the lungs, i e., a decreased output of the right ventricle, during attacks. Weiss and Robb used a dye method to measure the output of the left ventricle This method must be considered far from being satisfactory. However, in a large series of cases, they found low or normal cardiac outputs during paroxysmal dyspnea.

Lenègre and Scébat (1952) measured the

pulmonary arterial pressure and the pulmonary wedge pressure in 13 cases of pulmonary edema (two of them preceding catheterization). The pulmonary wedge pressure rose in all cases reaching from 35 to 45 mm Hg. At the same time, the pulmonary arterial pressure rose by about 30 to 50 per cent. These data were accepted as indicating a consistent rise of pulmonary capillary pressure above the level of the colloid osmotic pressure of the blood. The foregoing figures are similar to those of Gorlin et al. (1951), who found pressures of 32 to 54 mm Hg during episodes of pulmonary edema in mitral stenosis.

Roentgenology in acute pulmonary edema

FELIX G. FLEISCHNER

Acute pulmonary edema is set apart clinically by its paroxysmal character It may occur as a deterioration of pulmonary congestion More often, however, it occurs without preceding congestion In many instances, acute pulmonary edema is characterized also by a particular roentgenographic appearance, and this fact justifies a special discussion

As roentgenographic examination of the chest is increasingly used in more acute conditions, perihilar densities of a particular shape in pulmonary edema were observed by early authors (Day et al, Roubier and Planchu, Zdansky, and others). The term *butterfly density* was introduced by Nessa and Rigler, *batwing shadow*, by Hodson; *central*

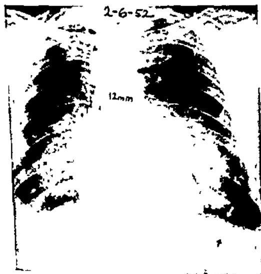

Fig 18-10 Man, aged 49 years Acute central pulmonary edema (type 1) This patient with a past myocardial infarct suffered from an upper respiratory infection while in a stage of borderline compensation. Bilateral central consolidation is seen, leaving the outer two-thirds of the lung fields clear There are also bilateral pleural effusion and a thick left "diaphragm" (arrows) revealing fluid between lung and diaphragm.

Fig. 18-11. The patient recovered with bed rest, antibiotics, and digitalis, losing 15 lb through diuresis The hilar vessels are still engorged, but otherwise the lung fields are clear. Notice the thin left "diaphragm" The azygos vein, previously 12 mm wide, now measures only 6 mm.

pulmonary arterial pressure and the pulmonary wedge pressure in 13 cases of pulmonary edema (two of them preceding catheterization). The pulmonary wedge pressure rose in all cases reaching from 35 to 45 mm Hg. At the same time, the pulmonary arterial pressure rose by about 30 to 50 per cent. These data were accepted as indicating a consistent rise of pulmonary capillary pressure above the level of the colloid osmotic pressure of the blood. The foregoing figures are similar to those of Gorlin et al. (1951), who found pressures of 32 to 54 mm Hg during episodes of pulmonary edema in mitral stenosis.

with uremia are frequently accompanied by episodes of pulmonary edema is probably due to arterial hypertension and left-sided failure (Luisada), possibly also to a generalized capillary damage in glomerulonephritis.

The known facts on the causes and pathology of pulmonary edema do not explain this particular central distribution of edema and the sparing of the periphery Structural or physiologic differences between the central and peripheral portions of the lung had to be sought (Kerley), and several attempts in this direction have been made

Marchand showed that rich connective tissue extended from the mediastinum along bronchi and vessels as far as the third or fourth division. He thought that pulmonary transudate would accumulate along these paths. By experiments with injection of opaque media on cadavers he produced "butterfly shadows."

Herrnheiser and Hinson confirmed (by the use of the whole section technique of Gough and Wentworth) that the *central arrangement* of edema exists also in the pathological specimen, that, in anthracotic lungs, there is a different distribution of coal dust in the central and peripheral portions, suggesting a difference of lymph drainage in these two portions. They subdivided the lung into root, medullary, and cortical parts of the lobes, according to anatomical differences The vessels branch in different fashion In the *cortical, peripheral portion*, they divide proportionately, in the *medullary, central portion*, mostly in a disproportionate fashion. It is assumed that this disproportionate confluence of veins and lymphatics interferes with proper drainage.

The concept that not all arteries are permanently perfused but that individual arteries and even whole areas are temporarily shut down as "block-arteries" (Sperrarterien) has been revived. Prichard et al have shown by angiography that sometimes the vessels in the periphery of the lung do not fill. Zdansky emphasized the effect of the ventilatory excursion upon the blood circulation and lymph drainage (Tendeloo; Drinker and Warren). Under the conditions prevailing during pulmonary congestion, the blood velocity is decreased causing increased transudation in areas of restricted ventilation, and the lymph current is slowed down causing reduced resorption. The central portions of pulmonary parenchyma wedged in the angles between the bigger vascular and bronchial trunks undergo apparently less ventilatory play. In the case of circulatory imbalance, transudate would be readily accumulated there, while the cortical portions, undergoing wider ventilatory excursions and better lymph drainage, would be kept dry.

These anatomicophysiologic factors, individually or together, apparently come into play under the sudden impact of circulatory disturbances of a certain degree. Thus central edema is not present, or it may be obscured, when chronic congestion preexists, and it is not seen in severe massive edema which drowns the lung all the way out to the pleura These factors satisfactorily explain the otherwise enigmatic roentgenographic appearance of acute central pulmonary edema.

edema by Gould and Torrance. (Fig. 18-10.)

Two representative subgroups may be described. In both instances the changes are rather symmetrical. In one type there are rather dense, almost homogeneous shadows occupying and surrounding the hilar regions, extending not more than half way to the periphery (Fig. 18-11). The lateral contours of these shadows are rather fuzzy. The remaining wide peripheral zone, apex, and lateral and basal portions of the lung field show normal or almost normal radiance The other type is even more surprising (Fig 18-12). The shadow is usually less dense, more of a blotchy-confluent type. It extends further toward the periphery but does not reach the chest wall. Again, the apical, lateral, and basal zones remain clear, this time for a width of only 2 to 4 cm In these instances, the edge of the zone of edema is often amazingly well contrasted against the clear peripheral zone. In the posteroanterior view, there is usually a waistlike indentation corresponding to the lesser interlobar fissure on the right, with corresponding interlobar indentations in the lateral view. In both types, a small or medium-sized pleural effusion is usually present. This represents the most characteristic, fully developed picture. Complications may modify it. This is true in the case of preexisting disease, e g, tuberculosis, fibrosis, and bullous emphysema, and in that of concurrent or collateral disease, such as pneumonia or infarcts. The early beginning may present less characteristic pictures, only faint, flecky haziness in the central lung fields. The clearance may be rapid; it usually begins at the periphery. In other instances it may proceed in the opposite direction, leaving mottled or ribbonlike shadows for a number of days; the nature of these shadows could not be guessed out of context with the clinical history and with previous or later roentgenograms.

Fig. 18-12. Man, aged 46 years Acute pulmonary edema (type 2) Classical "butterfly shadows" This patient had repeated myocardial infarcts; most episodes were accompanied by acute pulmonary edema of this type. There was no nitrogen retention and, at necropsy, no renal disease was found. On the left, the dense central shadow stands out, well defined, against the clear surrounding cortex of the lung. On the right, the waist indentation, caused by the horizontal fissure, partially blurs this identical arrangement. Here again, pleural effusion is found between lung and diaphragm, and is readily recognized on the left (arrow).

Edema fluid is found in the interstitial spaces and also in the alveoli and bronchioles, this may vary from a clear transudate to a cellular, albuminous, sticky or hemorrhagic exudate In instances of recurrent edema, hyaline membranes often line the alveoli and plug bronchioles (Bass et al.). None of these observations, however, have been found to be related to a specific causation or particular distribution of the edema.

The unusual butterfly arrangement of the edema, however, stimulated speculation as to its cause This was enhanced by the complexity of the entire problem, by the fact that this particular distribution had never before attracted attention, and by the fact that some of the earlier observations had been made on patients with renal disease Thus, from "pulmonary edema in patients with cardiorenal azotemia" (Roubier and Planchu), developed "pulmonary manifestations of azotemia" (Rendich), to "uremic edema" (Doniach). Soon, however, it became clear that some renal patients with a low nonprotein nitrogen had edema, that the majority of uremic patients do not have pulmonary edema, and that the same butterfly edema is seen much more commonly in nonrenal patients without uremia. Furthermore, no apparent relation between nitrogen retention and pulmonary edema is known (Altschule). That acute and chronic nephritis

quently caused pulmonary edema in the rabbit. Welch (1878) performed similar experiments in rabbits, with the exceptions that the ligature was placed distad to the left subclavian artery and that two of the three great vessels coming off the arch were also tied off; pulmonary edema occurred in these animals. These results could not, however, be obtained in dogs by Sahli, and appeared only in some experiments of Kotowschtschikow. More recently Antoniazzi repeated Welch's experiments in rabbits and only occasionally obtained pulmonary edema, unless the aorta was ligated *without opening* the thorax and without anesthesia. He further observed that previous injection of anesthetics or stellate ganglionectomy prevented pulmonary edema

Sarnoff (1958) has repeated Welch's experi- [illegible] that a dramatic venocon- [illegible] by low pressure in the aorta below the ligature. Such venoconstriction obviously tends to shift a large mass of blood towards the lungs.

INTERFERENCE WITH LEFT VENTRICULAR FUNCTION

By means of manual compression and the use of clamps, Welch produced pulmonary edema in rabbits. Similar experiments were repeated by Loewit, Alexandrow, Sahli, and Kotowschtschikow with inconsistent results in rabbits and rare positive results in dogs. The last two authors named concluded that Welch's results represented agonal changes.

Montanari improved the technique, cutting down in rabbits the size of the left ventricle in contact with the circulation by means of sutures His animals survived without respiratory difficulty unless more than two-thirds of the ventricle was excluded, in this case the animals died rapidly, only rarely showing pulmonary edema A different approach was that of Coelho and Rocheta These authors injected silver nitrate or alcohol into the wall of the left ventricle in dogs, causing pulmonary edema in a large percentage of animals. The significance of these striking findings was, however, put in question by the author's coworker, Cataldi, who obtained the same results (with slightly lower percentage) by injecting the irritating substances into the right ventricle. Cataldi found hypertension of the pulmonary artery and decrease of systemic arterial pressure in animals with this form of pulmonary edema, *irrespective of whether* the pulmonary edema was due to a right or left ventricular lesion.

Attempts were made by Cataldi and by Rubino (in the author's laboratory) to precipitate pulmonary edema in the dog by ligating either the right or left coronary artery, with inconsistent results. (This was due partly to the necessary opening of the chest and positive-pressure respiration, and partly to the effects of anesthesia.) The effect on the cardiovascular dynamics of ligation of either artery was the same, i e, there was a slow decrease in pressure in both pulmonary artery and aorta.

OBSTRUCTION OF PULMONARY VEINS

Attempts have been made to induce pulmonary edema mechanically by obstructing the pulmonary veins. Welch claimed to have observed its occurrence in his experiments on rabbits but Lowit and Antoniazzi could not confirm his findings. Altschule used a somewhat different approach to the same problem. He introduced a balloon into the left atrium through the auricular appendage and connected it to a rubber tube running out through the chest wall Inflation of the atrial balloon failed to produce pulmonary edema even though inflation lasted in some experiments until the animal died, hours later. However, it is true that pulmonary vein occlusion causes pulmonary venous hypertension, as proven by Denolin et al. (1957).

INJECTION OF EPINEPHRINE

It has been known for many years that intraveneous injection of epinephrine in rabbits induces pulmonary edema (Huchard and Claude; Josué, Cavina; Meltzer; Auer and Gates). Since pulmonary edema can be induced in this manner only in rabbits and other small laboratory animals, it is disputable if this phenomenon can be related to the clinical syndrome in man. It is, however, a useful method for inducing pulmonary edema in large groups of animals so as to study the pathological physiology of the process as well as the effects of therapy. The observations of the author, confirmed by Glass, Boggian, and Reinhardt, revealed that sedatives and narcotics (even when they do not induce anes-

I

Experimental pulmonary edema

ALDO A. LUISADA

Several methods have been employed for the experimental production of pulmonary edema. Indirect determinants are listed below.

HEART-LUNG PREPARATION

The earliest observations by Starling and coworkers on the heart-lung preparation recorded the spontaneous occurrence of pulmonary edema in such preparations. Evans pointed out that this phenomenon occurred much more frequently and rapidly in cat than in dog preparations Matsuoka studied the factors responsible for its occurrence and found that increased cardiac work was not a cause but that prolonged duration of the experiments "and general condition of the animal and the operation" were to be implicated He did, however, note the fact that increased pressure and passive dilatation in the pulmonary circuit favored the development of edema. Barry, Lambert and Gremels, and Newton concluded that the chief factor responsible for pulmonary edema in the heart-lung preparation was some change in the composition of the perfusing blood. Indeed, Lambert and Gremels described degenerative changes in the pulmonary vascular endothelium due to the action of this hypothetical toxin. Raising the arterial resistance, according to Matsuoka and Barry, favored the appearance of edema, and Newton reported that obstructing the outflow from the lungs also favored it. Barry, however, found that venous obstruction caused only congestion unless the blood were greatly diluted, under which circumstances edema might develop Anrep and Bulatao reported pulmonary edema when either ventricle failed.

INDIRECT DETERMINANTS OF EXPERIMENTAL PULMONARY EDEMA *

[illegible]

4 Compression or occlusion of left atrium
5 Valvular defects aortic insufficiency, mitral in-
[illegible]

B [illegible]
C Arterial hypotension, shock, hemorrhage
D Embolism

II Alterations of the central nervous system
A Brain lesions compression or stimulation

III Alterations of the peripheral nervous system
A Vagotomy
B Vagotomy with tracheotomy
C Faradic stimulation of lung root

IV Alterations of the respiratory system
A Airway obstruction inspiratory, expiratory, inspiratory and expiratory
B Hypoxia with heart overload or failure
C Respiratory burns and heat
D Drowning
E Intratracheal fluids
F Chest wounds
G Blast

V [illegible]
[illegible] amine), picrotoxin, nicotine
B Lung-irritant gases, oxygen poisoning
C Other agents alloxan, ammonium ion, thiourea compounds, methylene violet, methylene blue, methyl salicylate; acetic, sulfuric, and butyric ether, acetic ether and iodide solution, amyl salicylic ether, iodine and sodium iodide solution, iodoacetamide, bile and bile salts, urethane, carbon monoxide, carbon dioxide, barbiturates
D Metabolic effects alkalosis, hypoglycemia

VI Miscellaneous
A Hyperthermia, sensitivity phenomena mechanical irritation of the bronchus

* Pulmonary edema has been induced by the methods indicated in each of the subheads

SOURCE From Visscher et al., 1956

INCREASED STRAIN ON THE LEFT VENTRICLE

Friedlander (1873) found that ligating the aorta proximal to the innominate artery fre-

quently caused pulmonary edema in the rabbit. Welch (1878) performed similar experiments in rabbits, with the exceptions that the ligature was placed distad to the left subclavian artery and that two of the three great vessels coming off the arch were also tied off; pulmonary edema occurred in these animals. These results could not, however, be obtained in dogs by Sahli, and appeared only in some experiments of Kotowschtschikow. More recently Antoniazzi repeated Welch's experiments in rabbits and only occasionally obtained pulmonary edema, unless the aorta was ligated without opening the thorax and without anesthesia. He further observed that previous injection of anesthetics or stellate ganglionectomy prevented pulmonary edema.

Sarnoff (1958) has repeated Welch's experiments and proved that a dramatic venoconstriction follows the ligation of the aorta. This was considered as a reflex phenomenon caused by low pressure in the aorta below the ligature. Such venoconstriction obviously tends to shift a large mass of blood towards the lungs

INTERFERENCE WITH LEFT VENTRICULAR FUNCTION

By means of manual compression and the use of clamps, Welch produced pulmonary edema in rabbits Similar experiments were repeated by Loewit, Alexandrow, Sahli, and Kotowschtschikow with *inconsistent* results in rabbits and rare positive results in dogs. The last two authors named concluded that Welch's results represented agonal changes

Montanari improved the technique, cutting down in rabbits the size of the left ventricle in contact with the circulation by means of sutures. His animals survived without respiratory difficulty unless more than two-thirds of the ventricle was excluded, in this case the animals died rapidly, only rarely showing pulmonary edema. A different approach was that of Coelho and Rocheta These authors injected silver nitrate or alcohol into the wall of the left ventricle in dogs, causing pulmonary edema in a large percentage of animals. The significance of these striking findings was, however, put in question by the author's coworker, Cataldi, who obtained the same results (with slightly lower percentage) by injecting the irritating substances into the right ventricle Cataldi found hypertension of the pulmonary artery and decrease of systemic arterial pressure in animals with this form of pulmonary edema, *irrespective of* whether the pulmonary edema was due to a right or left ventricular lesion.

Attempts were made by *Cataldi and by* Rubino (in the author's laboratory) to precipitate pulmonary edema in the dog by ligating either the right or left coronary artery, with inconsistent results. (This was due partly to the necessary opening of the chest and positive-pressure respiration, and partly to the effects of anesthesia.) The effect on the cardiovascular dynamics of ligation of either artery was the same; i.e., there was a slow decrease in pressure in both pulmonary artery and aorta.

OBSTRUCTION OF PULMONARY VEINS

Attempts have been made to induce pulmonary edema mechanically by obstructing the pulmonary veins. Welch claimed to have observed its occurrence in his experiments on rabbits but Lowit and Antoniazzi could not confirm his findings. Altschule used a somewhat different approach to the same problem. He introduced a balloon into the left atrium through the auricular appendage and connected it to a rubber tube running out through *the chest* wall. Inflation of the atrial balloon failed to produce pulmonary edema even though inflation lasted in some experiments *until the animal died, hours later However, it* is true that pulmonary vein occlusion causes *pulmonary venous hypertension*, as proven by Denolin et al (1957).

INJECTION OF EPINEPHRINE

It *has been known for many years that* intravenous injection of epinephrine in rabbits induces pulmonary edema (Huchard and Claude, *Josué*, Cavina, Meltzer, Auer and Gates). Since pulmonary edema can be induced in this manner only in rabbits and *other small laboratory animals*, it is disputable if this phenomenon can be related to the clinical syndrome in man. It is, however, a useful *method for inducing* pulmonary edema in large groups of animals so as to study the pathological physiology of the process as well as the *effects of therapy The* observations of the author, confirmed by Glass, Boggian, and Reinhardt, revealed that sedatives and narcotics (*even when* they do not induce anes-

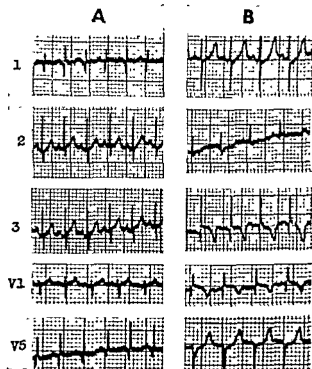

Fig. 18-13. Rabbit. Experimental attack of acute pulmonary edema A. Before injection of epinephrine. Five minutes later, a pattern of left ventricular "strain" had appeared. B Ten minutes after the injection and during pulmonary edema: right ventricular "strain"

thesia), diminish or prevent the edema of the lungs, while respiratory stimulants aggravate it. Luisada (1928b), Glass (1929), and Boggian (1929) showed that cutting all communications between the brain and the periphery prevents epinephrine pulmonary edema, and that previous one-sided sympathectomy, damage to the corpora quadrigemina, or bilateral stellate ganglionectomy also prevent its occurrence.

This method was later used by the author (1950) for evaluation of antifoaming therapy, and by Polli and Luisada (1957) for study of the effects of splenectomy, nephrectomy, and endocrine actions on pulmonary edema. The study of splenectomy extended older studies made by Tremonti (1930a)

A rabbit with acute pulmonary edema caused by epinephrine presents impressive changes of the electrocardiogram (Fig. 18-13) In the first stage, the pattern of *left ventricular "strain"* can be noted, obviously caused by the extreme systemic hypertension However, after a few minutes, this pattern is substituted by that of *right ventricular "strain,"* which is probably the result of the pulmonary edema (Fig 18-13B).

LEFT VENTRICULAR STRAIN

Aortic insufficiency was caused in the dog by cutting one of the leaflets of the aortic valve (Paine et al, 1952). The strain of the left ventricle was further increased by intravenous injection of epinephrine, central nervous system stimulation, or unilateral nephrectomy plus contralateral narrowing of the renal artery, leading to pulmonary edema.

INTRAVENOUS INFUSIONS

Since the studies of Cohnheim and Lichtheim, attempts have been made to induce pulmonary edema by means of injections of salt solutions of various concentration. These authors could not induce it regularly with large amounts of normal saline. Hallion and Carion claimed to produce edema of the lungs regularly with intravenous infusions of hypertonic saline solution, but Melli and Tasso could not confirm these findings. Warthin failed to induce pulmonary edema in dogs with intravenous injections of large amounts of isotonic saline solution. On the other hand, following bilateral vagotomy, edema of the lungs can be precipitated regularly by means of intravenous infusions (Kraus; Brunn; Farber).

Luisada and Sarnoff (1946) succeeded in obtaining pulmonary edema in the dog by very large, rapid intravenous infusions of either saline solution or plasma. They also showed that rapid *intracarotid* infusion toward the brain achieves the same result but with smaller doses and more consistently. They explained this effect as the result of a carotid sinus reflex. However, Luisada and Contro (1953) proved that *the carotid body* was involved (not the carotid sinus) and that lack of oxygen in the solution was more important than perfusion pressure. This interpretation was confirmed by the proof that carotid body stimulation causes a reflex dilatation of the pulmonary vessels which is mediated by vagal fibers (De Burgh Daly and De Burgh Daly, 1957). The same method was used by the author for evaluating the useful action of alcohol vapor administered by inhalation.

LESIONS OF THE CENTRAL NERVOUS SYSTEM

Von Frey first described the development of pulmonary edema following *vagotomy* (1867). Since then, a number of other authors have

observed the same phenomenon (Wolf; Schiff; Schafer, Weiser, Farber). Kraus, Brunn, and Farber found that pulmonary edema could be precipitated in vagotomized animals by intravenous infusion of fluids.

Farber studied the pathogenesis of pulmonary edema due to interference with the nerves to the lungs and found that the paralysis of the vocal cords is not a cause of the pulmonary edema, but that the real cause is the *loss of the innervation of the lungs.*

The fact that the sympathetic fibers are still intact was claimed, however, as the real cause by Jarisch, because removing the vagal impulses prevented the counteracting of the effects of the impulses of the sympathetic nerves (see below).

Other lesions of the central nervous system *may produce edema of the lungs.* Thus, Brown-Séquard found that stimulation of the stellate ganglia caused pulmonary edema. Joreš reported the occurrence of pulmonary edema after electrical stimulation of the hilus of the lung or the peripheral end of the cut vagus nerve, but Kotowschtschikow was unable to confirm his findings. However, when Teissier and Guinard combined stimulation of the peripheral end of the cut vagus nerve with *increased intrapulmonary pressure,* they claimed to have caused the development of pulmonary edema.

Jarisch et al. further showed that it is possible to provoke acute pulmonary edema in rabbits, rats, and guinea pigs by the suboccipital injection of veratrine. The edema may be prevented by injection of certain anesthetics (chloral hydrate and urethane), not by others; it may be prevented by large doses of atropine but not by cutting the vagus. The animals show an extreme arterial hypertension, severe tachycardia, and many signs of central excitation. The author and his coworkers (1957) used this method for the study of pulmonary edema in dogs. They showed through cardiac catheterization and transillumination of the lungs that, even though an increased venous return is the most important cause of pulmonary flooding, important pulmonary vascular reflexes also contribute to the increase of pressure in the pulmonary capillaries. A similar method, involving the injection of thrombin and fibrinogen into the cisterna magna was described by Cameron and De. This method was later used by Sarnoff and coworkers, who concluded that stimulation of the medullary centers produced increase of peripheral resistance (arterial and venous) and redistribution of the blood, followed by pulmonary hypertension.

IRRITATING SUBSTANCES IN THE LUNGS

Studies of pulmonary edema due to the inhalation of toxic or irritating substances have been made by many authors (Winternitz; Lambert; Mayer and Morel; Biondi, Melli). Changes in the permeability of capillaries caused by the action of toxic substances are well recognized and explain the pulmonary edema caused by war gases and other poisonings, and possibly that of pneumonia as well.

It has been known for many years that, after the inhalation of salt or fresh water, such as occurs in drowning, edema of the lungs develops, as manifested by the presence of large amounts of protein in the fluid in the lungs. Laqueur and De Vries Reilingh (1920) studied pulmonary edema due to inhalation of salt solutions and ascribed the resultant edema to the osmotic effect of the solution. Cameron and Neuberger (1937) showed that ketene has an action similar to phosgene and causes pulmonary edema in mice. They admitted a direct action on the protoplasm of the lung capillaries increasing permeability to plasma. Phosgene was also studied by Coman et al. (1947). Short (1942) had previously demonstrated that it causes a splitting of the mitochondria of the capillary endothelium, an early cellular response to injury. Cameron and Courtice (1946) showed that pulmonary edema is paralleled by a decrease in plasma volume and an increased concentration of the blood. As edema develops, pulmonary lymph flow steadily increases, as first shown by Drinker. Blood transfusion was proved extremely dangerous in experimental animals at this stage.

Ozone seems toxic for the capillary endothelium and causes pulmonary edema in mice (Mittler et al., 1956). Mittler (1958) further found that antifoaming agents do not help in this type of edema. Polli and Musiker (1958) produced pulmonary edema in rats by means of chlorine gas inhalation. They found that alcohol vapor or silicones administered by

aerosol were only moderately helpful, while parenteral morphine was seen to have a remarkably beneficial action. Rothlin successfully treated mild phosgene gas pulmonary edema with ergot alkaloids.

PULMONARY EMBOLISM

This type of experimental pulmonary edema has been studied by several authors including Katz et al. (1955) and Moreau et al. (1957). It is typical that localized embolism may cause diffuse pulmonary edema.

PULMONARY EDEMA DUE TO CHEST TRAUMA

Chest trauma, even if limited in extent, may cause diffuse, bilateral pulmonary edema. Daniel and Cate (1948) investigated the mechanism of this experimental form of edema and found that sympatholytic drugs prevented the diffusion and extension of the edema and saved the animals.

TOXIC PULMONARY EDEMA

Several poisons cause pulmonary edema in experimental animals. Among them, ingestion or intraperitoneal injection of ammonium salts causes pulmonary edema in cats, rabbits, rats, and guinea pigs, as shown by Windle et al. (1946), Koenig and Koenig (1948), McKay et al. (1949) and Cameron and Sheikh (1951). This type of pulmonary edema is usually preceded by severe hypertension and can be prevented or inhibited by adrenergic blocking agents. ANTU has a similar effect. *Alloxan* causes pulmonary hypertension and edema in the dog (Aviado and Schmidt, 1957). The most important cause of edema is a constriction of the pulmonary venules, as shown by the latter two authors and confirmed in the writer's laboratory.

13

Pathogenesis of paroxysmal pulmonary edema

ALDO A. LUISADA

The mechanism of production of pulmonary edema has been explained in different ways. Most writers have attempted to evolve *one* theory which might apply to all causes of pulmonary edema. It is the author's feeling that this is not feasible, and that different mechanisms should be advocated.

The oldest theory, advanced by Cohnheim and Welch (1878), postulated an *acute left ventricular failure causing a rise of* pulmonary venous pressure (backward failure), and then pulmonary edema. This theory met with wide acceptance, and is even now still invoked. Several objections can be raised: (1) Many patients with pulmonary edema exhibit a normal left ventricle, and the initial sequence of events involves either the central nervous system or the lungs, some patients have severe mitral stenosis or cor pulmonale, and the right ventricle is the only cardiac chamber under strain. (2) Patients with acute left ventricular failure may die in shock (cardiogenic shock) without pulmonary edema. This seems due to the fact that pulmonary capillary pressure rises only if there is good venous return to the right heart with a strongly active right ventricle.

A second theory was advocated by Teissier (1900). Disregarding cardiac elements, he considered pulmonary edema to result from an active, *sudden dilatation of the pulmonary vessels*. Even though this theory could not be accepted, reflex changes of the pulmonary vessels have been considered important by Cameron and Kuo, as well as by the author and his coworkers, who actually proved their existence. The following experimental data seem to confirm the importance of these reflexes in the production of pulmonary edema, even though they may also be interpreted according to a third theory (see below): (1) Bilateral stellectomy is effective in preventing pulmonary edema caused by intravenous epinephrine injection in the rabbit. (2) Rapid infusions produce different results, depending upon whether they are given intravenously or injected into the carotid arteries. Denervation of the carotid sinus area prevents this type of pulmonary edema. (3) Anesthetics, sedatives, and sympatholytic drugs are effective in preventing most types of pulmonary edema. Digitalis is poorly effective.

Another theory, already advocated by Peserico (1930), was revived by Sarnoff (1952), who called it "neurohemodynamic pulmonary edema." It emphasizes *the massive displacement of blood from the greater to the lesser circulation*, caused by strong sympathetic stimulation, acting on the peripheral vessels.

Theoretically, it is possible to distinguish between intracellular, *interstitial, and intraalveolar* types of edema of the lungs. Logically, the latter is the final stage, which is necessarily preceded by the others. Even though the first two stages are the most important in the mechanism of the edema, the third is the most vital for the patient because the alveolar fluid

TABLE 18-4. DIRECT DETERMINANTS OF PULMONARY CAPILLARY PRESSURES *
(from Visscher et al, 1956)

Variable	*Direction of change*	*Direct effect on pulmonary capillary pressure*	*Effect on pulmonary venous pressure*
Pulmonary arteriolar bore	Constriction	Fall	Fall
	Dilatation	Rise	Rise
Pulmonary venule bore	Constriction	Rise	Fall
	Dilatation	Fall	Rise
Pulmonary artery pressure (without arteriolar bore change)	Rise	Rise	Rise
	Fall	Fall	Fall
Pulmonary venous or left atrial pressure	Rise	Rise	(Pulmonary venous pressure is the determining variable)
	Fall	Fall	

* Considering in each case a change in only one variable at a time

prevents an adequate ventilation of the alveoli, thus impairing the gas exchanges in the blood. It is, moreover, important to consider the role of fluid having a high viscosity for the mechanics of alveolar respiration. According to Neergaard (1929), the surface tension of an extremely thin layer of fluid coating the alveolar endothelium is of great importance in the resistance of the lung to distention or compression A change in surface tension (plasma vs. water) might cause a complete transformation of pulmonary dynamics. Even more important would be the presence of fluid in the bronchioles Moreover, the viscous proteins of the bronchioles tend to "bubble," further increasing the volume of the exudate and its resistance to ventilation This point will be further discussed under "therapy" (antifoaming drugs).

Three elements are undoubtedly of paramount importance in the mechanism of pulmonary edema: (1) increase of pulmonary capillary pressure; (2) increase of pulmonary capillary permeability, (3) decrease of colloid osmotic pressure of the plasma. They will be examined separately and in detail.

INCREASE OF PULMONARY CAPILLARY PRESSURE

It is obvious that any study of this factor should include a complete consideration of all cardiac and vascular elements which may affect pulmonary capillary pressure. Because of the dynamic connections between greater and lesser circulations, both of them should be investigated.

An extensive literature is available on the dynamics of the pulmonary circulation in various types of animal preparations (Table 18-4). The applicability of these observations to clinical conditions is difficult to evaluate for several reasons: (1) the unphysiological nature of the animal preparations including the introduction of measuring devices into various parts of the pulmonary circulation,[1] and frequently accompanied by a good deal of shock; (2) the cutting of nerves which, though it may bring out mechanical relations, yields results which have no necessary similarity to the physiology of the intact animal, (3) use of anesthesia and artificial respiration, which are known to alter cardiac and respiratory dynamics; (4) differences between animal species; and (5) lack of unanimity concerning results reported by different investigators. Another source of difficulty is possibly the fact that a majority of the studies on the pulmonary circulation are based on changes in pressure in its various portions, whereas Hochrein and associates have shown that enormous changes in the volume of the capillary bed may occur as a result of altered dynamics.

[1] In this respect, modern techniques are definitely better than older ones. At present, catheterization of both halves of the heart can be done in animals with closed chest and limited trauma.

with little or no change in pressure This is probably connected with the negligible resistance to dilatation of the pulmonary capillaries due to the absence of significant tissue pressure, such as is found elsewhere in the body.

In the *heart-lung preparation*, according to Fuehner and Starling, increasing the strain on the left ventricle by increasing the peripheral resistance causes a rise in pressure in the pulmonary circuit. However, Anrep and Bulatao criticized these experiments on the basis that the inflow into the right ventricle was not maintained at a constant level[2] Welch and Kotowschtschikow noted a proportionate rise in pulmonary arterial pressure, when the aortic pressure increased following ligation of this vessel, by leaving open some of the large arteries of the aortic arch Katz and Wiggers found that ligating the aorta in a relatively intact animal caused no change in pulmonary arterial pressure On the other hand, in open chest experiments, every increase of inflow to the right heart, and every increase in the load on the left ventricle raises the pulmonary vascular pressures (Weber, and many others)

Lambert and Gremels found that a rise in pulmonary arterial pressure occurs in heart-lung preparations when pulmonary edema is developing, it is impossible to state whether the change in the pulmonary arterial pressure is related to the cause or effect of the pulmonary edema Cataldi found that the development of pulmonary edema in animals following the injection of irritating substances into the ventricular wall was also associated with a rise in pulmonary arterial pressure and a fall in systemic pressure, irrespective of whether it was the left or the right ventricle which was damaged. Farber described in detail the gross and microscopic changes in the lungs during the development of pulmonary edema in animals He observed the fact that frank pulmonary edema is always preceded by a period during which only intense congestion is present.

Of importance are the observations of a number of authors on pulmonary edema of diverse origin, in various types of preparations (Matsuoka, Newton, Barry, Kraus, Brunn, Farber), indicating that, whenever the tendency toward the formation of edema of the lungs is present, its development is favored by whatever causes slower circulation or increase in the volume of the blood in the lungs.

Left atrial and pulmonary arterial pressures were measured in the dog by Renais et al. after injection of hypertensive drugs followed by saline infusions. According to them, left atrial hypertension was constant. Pulmonary edema occurred when left atrial pressure was higher than 30 mm Hg. Welch's theory of pulmonary edema postulated "a disproportion between the working power of the left ventricle and that of the right ventricle of such character that, the resistance remaining the same, the left heart is unable to expel in a unit of time the same quantity of blood as the right heart" As Visscher pointed out, Welch did not postulate a prolonged imbalance in output, obviously inconceivable, but only admitted a temporary imbalance leading to overfilling of the pulmonary bed Several factors may cause an increase of pulmonary capillary pressure.

1. *A high pressure of the pulmonary capillaries always follows an increase in the mean pressure of the left atrium due to increase of diastolic pressure in the left ventricle.* Obviously, the latter may be due to (1) weakness of the left ventricle (myocardial infarct, rheumatic carditis, metabolic disturbance, i e, *absolute left ventricular*[3] *failure*), or (2) inadequacy of the left ventricle to empty itself completely in the presence of extremely high peripheral resistance or extremely high venous return (hypertensive crisis, extreme vasoconstriction with redistribution of the blood, thyrotoxicosis, beriberi, anemia, i e, *relative left ventricular failure*) Animal experimentation usually succeeds in provoking pulmonary edema through the second mechanism but, in clinical cases, the first may operate too, though possibly only as a concomitant factor The combination of the two (absolute plus relative weakness of the left ventricle) is probably common

The studies of Sarnoff have proved that a

[2] The tremendous increase of coronary flow gave an increased inflow to the right heart

[3] As a good output of the right ventricle is necessary for the production of pulmonary edema, it is obvious that a moderate left ventricular failure is more effective than a severe one Dramatic left ventricular failure usually causes cardiogenic shock and not pulmonary edema.

redistribution of the blood and an increase in venous return to the right heart, associated with an overload of the left ventricle, is the basis of the "neurohemodynamic pulmonary edema."

2. *A high pressure of the pulmonary capillaries always follows an increase of mean left atrial pressure without increase of left ventricular diastolic pressure.* This is typically found in cases of *mitral stenosis* (mitral block) or *insufficiency*. Clinically, mean pressures of 35 to 40 mm Hg can be observed without pulmonary edema. As these pressures are higher than the colloid osmotic pressure of the plasma,[4] it is likely that collateral pulmonary-bronchial anastomoses, well developed lymphatic drainage, and possibly structural changes of the capillary walls prevent the edema to a certain extent.

3. *High pressure of the pulmonary capillaries always follows constriction of the pulmonary veins.* This may be caused by the action of circulating substances (Mautner and Pick, Luisada; Aviado) or vascular reflexes, as proved in the author's laboratory (Aravanis et al).

It is obvious that *any increase in systemic venous return* or *intracardiac left-to-right shunt* will cause an important increase of pulmonary capillary pressure if there is left ventricular failure, mitral block, or pulmonary vein constriction On the other hand, pulmonary arterial constriction, while overloading the right ventricle, would *decrease* the pressure in the pulmonary capillaries and thus tend to prevent the edema (Table 18-4)

Whether or not *an acute dilatation of the pulmonary arterioles* may contribute to the edema in some cases, is an unsolved problem This possibility should be considered particularly in certain cases (mitral patients, congenital shunts), where pulmonary arterial constriction seems to prevent flooding of the capillaries Any relaxation of this vasoconstriction would favor pulmonary edema

Several researchers have investigated the possibility that nerve impulses, *directly acting on pulmonary vessels,* may influence the occurrence of pulmonary edema. Obviously, two possibilities were considered: (*a*) changes in caliber of arterioles, venules, or capillaries, or (*b*) changes in capillary permeability.

In one series of studies, Ferguson and Berkes (1957) submitted the lungs of animals to high arterial pressures (50 to 90 mm Hg in the arteries) while left atrial pressures were normal (4 to 5 mm Hg). *Edema occurred in denervated lungs at lesser pressures than those tolerated by innervated lungs.* This would lead to the belief that sympathetic tonus (of the arterioles?) is beneficial in preventing pulmonary edema.

Pulmonary edema caused by *vagal section is not affected by atropine and is prevented* by isopropylarterenol, as proved by Schmitt and Meyers (1957). This was interpreted as indicating that *a reflex loss of sympathetic tonus,* caused by vagal section, was involved (loss of afferent vagal impulses). Sympathetic inhibition prevents pulmonary edema caused by rapid intracarotid infusion, intravenous epinephrine, trauma to the chest, cisternal injection, ammonium-salt administration, or aortic ligation; this is undoubtedly due in large part to the effects on systemic vessels, but one might also postulate that changes of the sympathetic tonus of the pulmonary vessels are important in the mechanism of pulmonary edema. The last, still-missing link, is the demonstration whether this effect is purely mechanical or due to humoral agents

4. *Pulmonary capillary pressure* is increased by (*a*) redistribution of the blood with increase of pulmonary blood volume; or (*b*) increase of circulating blood volume. This fact, carefully investigated by Korner (1953) seems to be due to a *higher volume elasticity coefficient of the left atriovenous system in comparison with the right* (Opdyke et al , 1948).

CAPILLARY PERMEABILITY

Filtration Area. According to Visscher et al , there is an increase in filtration area whenever a larger number of alveolar capillaries are open. Increase of pulmonary capillary pressure, whatever the cause, would increase the filtration area.

Membrane Permeability. There seems to be a *linear relationship* between mean hydrostatic pressure in the capillaries and osmotic pressure of plasma proteins. With normal blood volumes, only the smaller particles escape from the blood; with increase in volume,

[4] This pressure was considered equivalent to 25 mm Hg by Starling; Fleury quotes the value of 32 mm Hg *in man.*

larger particles escape and appear in the lymph (Mayerson; Wassermann et al, 1955). This seems to prove that permeability of the wall is directly influenced by the degree of distention, a fact which had already been postulated by Krogh (1923).

Pulmonary edema fluid may vary considerably in protein content (Visscher et al) but this sheds no light on the mechanism for several technical reasons, including the possibility of addition of water in the air passages.

Membrane Damage. Observations in phosgene pulmonary edema (Hebb and Nimmo-Smith) seem to indicate that the disturbance occurs without changes of pulmonary capillary pressure[5] Then, two possibilities should be considered. direct damage to the endothelium or liberation of edematogenous substances

Hypoxia. The role of hypoxia in increasing pulmonary capillary permeability was stressed by C. Drinker However, several weaknesses of his theory were pointed out by Visscher et al including the fact that he ignored the role of changes in pulmonary venous pressure as a result of hypoxia

Capillary-wall Rupture. Microscopic or gross hemorrhages in the lungs are common in pulmonary edema. While "fragility" of the capillaries may be increased by poisons and inhalant gas, it is obvious that, in most cases, rupture of the capillary walls is caused by severe increase of internal pressure This has been confirmed by Kisch through use of the ultramicroscope.

Secretory Function of the Endothelium? The process of pulmonary edema has been investigated in experimental animals by Kisch (1958) by means of the electron microscope He demonstrated that, during an attack, both the ciliated and nonciliated cells secrete droplets of protein into the alveolar ducts (Fig. 18-14) This process requires further investigation because it may be of extreme importance in elucidating the mechanism of edema if some of the fluid is secreted by other cells than those of the capillaries.

Edematogenous Substances Acting on Permeability? The possibility that specific substances may act on capillary permeability was discussed by the author in 1930. At that time, *histamine* and *acetylcholine* were particularly considered. More recently, *serotonin* has been added. Serotonin seems to have several effects on the lungs. on the one hand, it constricts the arterioles and dilates the capillaries; on the other, by acting on a "permeability-globulin precursor," it seems to increase permeability of the endothelia (Spector, 1957). Both histamine and serotonin seem to have a similar mechanism and both are inhibited by several so-called "antihistaminic" drugs. If this mechanism is accepted, certain humoral connections, so far poorly understood, become clear. Splenectomy, useful in experimental pulmonary edema of the rabbit (Tremonti; Polli and Luisada) could act by preventing a sudden liberation of serotonin by the contracting spleen. Heparin, found useful in experimental pulmonary edema of the dog (Luisada and Contro) might act by inhibiting this mechanism (Spector). Further, the useful effect of adrenocortical steroids in preventing pulmonary edema (Schlechter et al., Polli and Luisada) could be, at least partly, connected with this same mechanism.

[5] Experiments in progress in the author's laboratory seem to confirm this in chlorine gas pulmonary edema.

DECREASED OSMOTIC PRESSURE OF THE BLOOD

This occurs after prolonged saline infusions, in lipoid nephrosis, starvation, or liver diseases As the effect of this factor is widespread, pulmonary edema due to decreased osmotic pressure is either part of a diffuse anasarca or is favored by other factors acting on the lungs.

GENERAL CONCLUSIONS

It should be kept in mind that most elements of pulmonary edema are interrelated· chemical and endocrine products may cause vasoconstriction and changes of permeability, blood pressure changes may cause reflex release of hormones or chemicals, and neurogenic elements may act through either the vasomotor system or hormones Moreover, the part played by the various factors differs according to the various causes and associated elements of pulmonary edema

Certain conclusions reached by experimental workers have a special importance.

Stimulation of the brain or the carotid body leads to direct or reflex *stimulation* of the sympathetic system, followed by severe vaso-

A

B

Fig. 18-14. A. Alveolar duct of a rabbit in acute pulmonary edema. ×13,000. One ciliated (C) and three nonciliated cells (NC) with their nuclei (N). The arrows indicate fine droplets, one of them still connected with the cell. In the ciliated cell, vacuoles near the surface, one of them (x) seems to just penetrate the surface. B. From the same animal, one ciliated and one nonciliated cell. Arrows indicate bunches of little droplets, still connected with the cell. On top, a big droplet in contact with some cilia. Pictures (A) and (B) prove that the epithelial cells are the source of part of the fluid produced in pulmonary edema. Under normal conditions, the secretion of these cells can be seen only rarely and very sparingly. (*Courtesy of B. Kisch.*)

constriction. This leads to increased peripheral resistance with increased loading of the left ventricle; displacement of a large mass of blood from the arterioles, capillaries, and blood reservoirs towards the veins, increased venous return; and, finally, filling of the blood vessels of the lungs with a large quantity of blood. In other words, this stimulation causes an increased output of the right ventricle, and, at the same time, increased difficulty in the emptying of the left ventricle This mechanism assumes great importance if there is left ventricular strain, and even more so if there is left ventricular failure Whether or not it is sufficient to cause pulmonary edema when the heart is intact is still open to question

MECHANISM OF CLINICAL FORMS OF PULMONARY EDEMA

The following considerations attempt to explain some clinical forms of pulmonary edema

Pulmonary Edema Following Massive Myocardial Infarction. When the power of the left ventricle is suddenly decreased, there occurs a marked increase of left atrial and pulmonary capillary pressures However, the latter persists only if an adequate venous return is maintained Therefore, a severe (but not too severe) lesion of the ventricle is the most effective. A peripheral mechanism initiated by cerebral ischemia, carotid-sinus hypotension, or carotid-body hypoxia, may contribute to the disturbance by causing peripheral vasoconstriction The accumulation of blood in the lungs is therefore probably due to both a cardiac and a vascular mechanism

Pulmonary Edema of Patients with Hypertension, Aortic Insufficiency, or Aortic Stenosis; of Cases with Minor Coronary Attacks; and Following Transfusion in Surgical, Obstetrical, Anemic, or Cardiac Cases. Left ventricular strain is followed by increase of left atrial and pulmonary venous pressures. Excitement, exposure to cold, fear of death, or exertion cause sympathetic stimulation and redistribution of the blood, with its accumulation in the lungs, thereby favoring acute pulmonary edema. The increased peripheral resistance may transform ventricular strain into ventricular failure. Or else, transfusions or infusions further favor the edema by increasing the quantity of blood in the lungs and lowering osmotic pressure.

Pulmonary Edema of Nephritic Patients, Especially If Uremic. A mechanism similar to the above can be postulated. Retention of metabolites increasing capillary permeability (nephritis), or decreased osmotic pressure of the blood (nephrosis), may be among the favoring causes.

Pulmonary Edema Following Trauma to the Skull or Lesion of the Central Nervous System. In this type, there is severe central sympathetic stimulation. This causes vasoconstriction and increased resistance placing a severe load on the left ventricle; it also leads to redistribution of the blood and its accumulation in the lungs. While these elements favor pulmonary edema, other factors should also be taken into consideration, such as dilatation of pulmonary arterioles or constriction of pulmonary venules and liberation of substances increasing capillary permeability (histamine, serotonin, hyaluronidase, etc).

Mitral Stenosis. The outflow of blood from the lungs is impeded by the mitral block, even during rest Sympathetic stimulation caused by excitement, exertion, exposure to cold, anger, or fright leads to (1) *tachycardia*, with shorter diastoles and impaired emptying of the left atrium, and (2) *vasoconstriction*, with redistribution of the blood and its accumulation in the lungs. The effect of the mitral block is proportionally increased by greater venous return to the heart

Exposure to Toxic Gases; Asphyxia. Here, the most important effect seems to be damage to the capillary endothelium followed by liberation of substances increasing capillary permeability. The role of reflexes arising in the mucosa of the respiratory passages is still to be evaluated These reflexes and the effect of hypoxia have special importance in cases of strangulation, asphyxia, or drowning

14

Therapy of paroxysmal pulmonary edema

ALDO A. LUISADA AND LUIGI CARDI

Considering the multiple causes and the various mechanisms which may be involved in pulmonary edema, it is not surprising that a multiplicity of drugs and physical methods has been employed in its treatment. Unfortunately, tradition, on the one hand, and erroneous concepts, on the other, have thus far prevented a rational approach; while little agreement exists between different groups of physicians, each group treats all cases of pulmonary edema in a similar method.

DRUG THERAPY

Morphine. The value of morphine has been demonstrated in various types of experimental pulmonary edema. Morphine terminates most of the mild and some of the severe attacks, the best results being obtained in cases with hypertension, uremia, or mitral stenosis. The untoward effect of morphine in cerebral episodes and in chronic cor pulmonale should limit its use in such cases. The deleterious effect of morphine on the fetus may indicate the need for a cautious use of this drug in attacks occurring during pregnancy Even in cases of coronary occlusion, large doses of morphine may favor the onset of shock.

The mechanism of action in morphine administration is not completely known. It depresses the respiratory center and decreases the suction effect of dyspnea (which in turn may decrease edema) In therapeutic doses, morphine causes no apparent changes in cardiovascular dynamics. Pulmonary arterial pressures of cardiac patients, studied by catheterization, decreased in 26 out of 34 cases, but increased in the other 8 (Lenègre). It is, therefore, difficult to foresee whether the effect of morphine will be beneficial in a given case. Alleviation of anxiety and interruption of harmful reflexes is a useful action of morphine, especially in coronary patients. Vomiting caused by this drug may be deleterious. Morphine decreases the basal metabolic rate; this should decrease the work of the heart and lower venous pressure. However, it may take time for this effect to become apparent.

Morphine is administered subcutaneously in doses of 10 to 15 mg. It may be given intravenously

Atropine. Atropine (or belladonna) was used empirically in England for a long time before any publication described its effect in pulmonary edema.

Atropine was found either mildly beneficial or harmful in animals, when pulmonary edema was induced by means of epinephrine or rapid intracarotid infusion. Atropine does not improve pulmonary edema caused by ingestion of ammonium chloride, while it is beneficial in pulmonary edema caused by lesions of the central nervous system. The latter effect seems due to its prevention of extreme bradycardia, one of the possible factors of pulmonary congestion.

The clinical use of atropine should be limited to neurologic conditions with bradycardia and to some cases of coronary occlusion, also presenting bradycardia. In other cases, the tachycardia caused by atropine, as well as vagal inhibition in general, may be detrimental. Bronchodilatation caused by atropine has been considered either harmful or useful according to different theories.

For the above reasons, *Demerol*, a drug with both an atropinelike and a morphinelike action, should *not* be preferred to morphine, except in cases with a definite indication for the use of atropine. Moreover, Demerol has only moderate effects in decreasing anxiety.

Barbiturates; Chloral Hydrate. Barbiturates and chloral hydrate have been shown to be of value in experimental pulmonary edema. Their intravenous administration in man was attempted long ago by Luisada (1928–1930) and their value in several cases of pulmonary edema was shown. However, these drugs may be ineffective and, in certain cases, one cannot escape the impression that the deep sedation produced by them hastens the patient's demise. Venous return is decreased by chloral and barbiturates, and it is only logical to avoid use of these drugs in patients of the second group, those in danger of shock.

Aminophylline. This drug is a mild vasodilator, a bronchodilator, and a stimulant of the respiratory center. The first action is useful, though inadequate, the second is of doubtful utility (see atropine), and the third is definitely detrimental. For these reasons, aminophylline should not be used in the emergency treatment of the attack. The routine use of aminophylline, practiced in certain hospitals, cannot be recommended.

Papaverine. Intravenous injection of papaverine in association with other drugs has been advocated by Luisada (1930). Papaverine is a smooth-muscle relaxant and a vasodilator. The usual dose is 100 mg intravenously. Possible objections to its use are (1) if the patient belongs to group 1 (high output), papaverine is too mild a vasodilator to be effective, (2) if the patient belongs to group 2 (low output), even a moderate decrease of venous return can be dangerous.

Amyl Nitrite. This drug is administered empirically by inhalation in some hospitals. It is very probable that its powerful vasodilator effect may be useful in certain hypertensive patients, in spite of its extremely short span of action. However, since this drug may dilate the pulmonary vessels, the authors do not recommend it, even in patients belonging to group 1. As far as patients in group 2 are concerned, the use of amyl nitrite presents the same dangers as that of other vasodilators.

Intravenous Calcium Gluconate. This drug, tried by Luisada in animals (1928) and man (1930) has been further used in clinical cases by Gubner. It is supposed to have a direct effect on capillary permeability but its moderate vasodilator action is probably contributing to its usefulness.

Mercurial Diuretics. Mercurial diuretics have been used intravenously for pulmonary edema in many hospitals. Empiric use of these agents undoubtedly rested on the hope of rapid dehydration obtained through the promotion of diuresis. This action, however, would hardly be adequate and timely for improving circulation during the attack. Another property of the mercurials was subsequently described when cardiac catheterization revealed that they cause an important drop of pressure in the right atrium and ventricle within 20 to 30 min. This drop in pressure is still unexplained, and may be due to venous constriction decreasing venous return. This effect should be considered useful in patients of group 1 (high output), but unwanted and possibly dangerous in patients of group 2 (low output).

Sympatholytic Drugs. Drugs inhibiting or preventing stimulation of the sympathetic system have been considered helpful, following the demonstration that bilateral stellectomy was useful in preventing pulmonary edema, and also that spinal anesthesia produced similar beneficial effects. In animals, sympatholytic drugs have been shown to favorably affect the course of edema caused by most experimental procedures. Like all hypotensive drugs, sympatholytics (*Dibenamine, Piperoxan, Hydergine*) and ganglionic blocking agents (*Arfonad*, tetraethylammonium chloride) may induce shock in patients of group 2. The lasting action of some of these drugs and the difficulty of counteracting their effect, whenever this proves to be harmful, are other definite disadvantages.

Digitalis Glycosides (Ouabain). According to the theory of left ventricular failure, attacks of pulmonary edema are caused by an acute

weakening of the left ventricle. Therefore, intravenous administration of drugs stimulating the myocardium, like *strophanthin (or ouabain)*, was advocated in the emergency treatment of these attacks and good results were claimed. More recently, intravenous *digitoxin* or *lanatoside C* was substituted for strophanthin, and in many hospitals intravenous digitoxin has become part of routine therapy. Small doses of ouabain have been advocated in pulmonary edema associated with cardiogenic shock.

This therapeutic concept presupposes (1) that the left ventricle can be stimulated (this may not be possible when the ventricular wall is damaged by recent coronary occlusion or by prolonged and severe coronary insufficiency); and, (2) that the right ventricle is not unduly stimulated by the drug, so that no further rise of pulmonary flow or pulmonary arterial pressure will take place. Both premises may be questioned in some of the cases

Digitalis glycosides may lower venous pressure; however, this effect is mainly due to improved function of the myocardium, and does not take place otherwise On theoretical grounds, digitalis and ouabain are useful in any of the many cases having only a "relative" failure, namely one caused by "overload" and not by metabolic imbalance. However, during the attack, digitalis glycosides may be detrimental to patients with myocardial infarction Experiments on the preventive or therapeutic effect of digitalization in experimental pulmonary edema have failed, so far, to show any benefit (Testelli and Musiker, 1959).

A special case should be made of patients with mitral stenosis In these patients, the high pressure of the pulmonary capillaries is caused by high right ventricular output in the presence of mitral obstruction Rapid digitalization, if performed during an attack, can increase the severity of the edema, and may even precipitate pulmonary edema by increasing right ventricular output while the outflow from the lungs is impeded by the mitral block. A striking demonstration was given by Lenègre Injection of 1.2 mg of digitoxin in a patient with mitral stenosis during catheterization was rapidly followed by pulmonary hypertension and pulmonary edema Morphine and venesection then lowered pulmonary pressure and caused cessation of foaming.

Antihistaminics; Antiserotonins. The concept that liberation of histamine was the final event preceding edema of the lung was advanced by Luisada and his coworkers (1950). This concept seemed to be corroborated by subsequent studies but is still far from being conclusively demonstrated. *Phenergan* seemed to give good results in experimental and clinical pulmonary edema. However, its usefulness was not confirmed. Some "antihistaminics" are also "antiserotonins" while all of them are central nervous system depressants. Therefore, the explanation of this effect may be different from that initially postulated. *Reserpine* seems to have useful effects in certain types of experimental pulmonary edema, a fact which might be explained by its antiserotonin action.

Heparin was found beneficial in pulmonary edema of the dog (Luisada and Contro). As other anticoagulants do not share this action, this effect might be attributed to modification of the serotonin permeability mechanism (see above) or, in general, to modification of capillary permeability.

Corticotropin (ACTH). Corticotropin has been found beneficial in acute pulmonary edema of rabbits. Considering that its effect was obtained after 4 days of treatment, this drug might be considered *in the prevention* of the clinical attacks, but not in their therapy.

PHYSICAL, PHYSICOCHEMICAL, REFLEX, AND SURGICAL TREATMENT OF PULMONARY EDEMA

Several physical or physicochemical procedures have been used. Some are effective and should be considered in certain cases.

A Hot Bath (Sitzbath). This procedure has been used empirically and may be of help, since it causes peripheral vasodilatation It is particularly indicated in patients with hypertension or aortic insufficiency.

Venesection or Application of Tourniquets. The former is an old procedure, which is extremely effective in patients with arterial hypertension or aortic insufficiency and in certain instances of mitral stenosis with high venous pressure. As the main result is decreased venous return, venesection is contraindicated in patients of group 2 because it may induce shock The general procedure is withdrawal

of 500 to 600 ml of blood from an antecubital vein by means of a 15 gage needle or after cutting the vein with a scalpel. If the *tourniquet* procedure is used, bindings are applied to the four limbs with a moderate pressure, each is released and reapplied every 20 to 30 min in order to avoid venous thrombosis.

Oxygen. Oxygen was used at first only on patients with pronounced cyanosis As hypoxia may occur in pulmonary edema either as a primary or as a secondary factor, the use of oxygen is undoubtedly rational Moreover, clinical improvement follows its use in certain cases It is unfortunate that foam in the bronchioles prevents oxygen from reaching many of the alveoli. Oxygen is usually administered in the form of 100 per cent oxygen and humidified in order to prevent drying of the mucosae As oxygen in high concentrations is irritant, its administration should be interrupted from time to time in order to allow periods of normal air breathing.

Pressure Respiration. Pressure respiration has been advocated in the treatment of pulmonary edema. The theoretical basis of this method is that the increased pressure in the bronchoalveolar system counteracts the high pulmonary capillary pressure and decreases transudation Following animal experimentation, Barach et al suggested breathing against a positive pressure of 3 to 6 cm water This procedure produced useful results in several clinical cases and seemed particularly indicated in pulmonary edema due to gas poisoning

It has been shown that positive-pressure respiration, by increasing intrapleural pressure, decreases venous return This procedure, which may be useful in patients of group 1, presents some danger in patients of group 2, where impending shock might be precipitated [1]

Spinal Anesthesia. Spinal anesthesia with Novocain was tried by Sarnoff and Farr with encouraging results in clinical cases of protracted pulmonary edema which were refractory to other therapy. The intensive vasodilatation which follows spinal anesthesia decreases venous return to the right heart and lowers pulmonary arterial pressure. It is likely that the mechanism of action and the contraindications of this technique are similar to those of sympatholytic drugs. It should be kept in mind, moreover, that *Novocain* was also found useful when administered by intravenous injection in clinical cases (Gottsegen and Kohen). The dose employed was 10 ml of 1 per cent solution Its mechanism is probably related to central nervous system depression, similar to that of the "antihistaminics" and sympatholytics.

Stellate Block. Stellate block proved useful in experimental pulmonary edema, when tried by a coworker of the author. Clinical use of this method was made in 1952 by Pierach and Stotz They blocked the right stellate ganglion with procaine in eight clinical cases of pulmonary edema with hypertensive, coronary, or rheumatic heart disease. Excellent results were reported The authors state that only the right ganglion should be blocked while block of the left would increase pulmonary congestion. Explanation of the mechanism of action, however, is only tentative

Compression of the Carotid Sinus. This procedure was advocated by Wassermann. It acts by causing a reflex vasodilatation. It is extremely effective in patients with hypertension and in general in those of group 1. It is contraindicated if there is danger of shock.

ANTIFOAMING OR DEFOAMING THERAPY

Pulmonary edema, whatever the initial cause, starts a vicious circle of events which tends to prolong the attack This cycle is based on high pulmonary capillary pressure, transudation and accumulation of fluid in the alveoli, foaming, and local hypoxia, which in turn leads to more transudation, more foaming, and more hypoxia. While procedures tending to lower pulmonary capillary pressure are undoubtedly the most effective in patients of group 1, these procedures are either poorly effective or actually dangerous in patients of group 2.

Since 1950, a new approach, that of attempt-

[1] While positive pressure obtained by an expiration valve definitely decreases venous return, positive-pressure respiration with modern apparatus causing *intermittent pressure respiration during inspiration* seems to increase intraalveolar pressure for only a brief time With this method, Miller and Sproule obtained good results in pulmonary edema, even when associated with shock. However, even this method seems to cause "profound disturbances of intrathoracic circulation" (Feinsilver, 1958).

ing to break the cycle by acting on the foaming process itself was tried in the authors' laboratory. It was shown long ago (Laqueur and De Vries Reilingh) that large amounts of fluid may be present in the air passages with little danger to life, as soon as the surface tension of the fluid reaches a critical point, foaming starts. This leads to extremely severe effects, partly through the enormous increase in volume (foam) and partly through modification of the normal alveolar function which is based upon surface tension effects between humid alveolar surface and air (Neergaard).

Since impairment of the normal gas exchanges of the lungs is followed by hypoxia, which favors increased permeability of the capillaries, the foaming process in itself may be responsible for the continuation of the attack, and may be a cause of death. If a modification of the surface tension of the foam is brought about, the bubbles burst, then, the fluid which formerly composed the thin separating layers, will occupy a smaller volume than the foam

Antifoaming or defoaming agents (ether, octyl alcohol, capryl alcohol, and ethyl alcohol) were tested in the form of vapors or aerosols in four different types of experimental pulmonary edema. While the use of long-chain alcohols did not seem to improve the outcome, ether had a mildly beneficial action and ethyl alcohol (ethanol) produced excellent results. The inhalation of oxygen with a high concentration of *ethyl alcohol vapor* was followed by a decreased mortality, a lower lung-body index, and the easy expectoration of fluid. The systemic effect of alcohol was slight, because it is only a mild sedative and vasodilator, and because of its poor absorption This was shown by the observation that beneficial effects of alcohol by other routes were obtained only when administered in doses which induced deep anesthesia.

Experimental studies have also been made by Reich et al. with *silicone* in ether or in water; both were found beneficial Several antifoaming agents including silicone mixtures were compared in experimental animals (Luisada and Cardi). Three agents were definitely beneficial. 10 per cent silicone in water, Freon, and ethyl alcohol Since Freon may present some dangers if administered for long periods, only alcohol and silicone were considered for clinical use. While alcohol yields superior results in experimental pulmonary edema induced by epinephrine, it has a moderately irritant effect on the bronchial mucosa. This should favor the use of aerosol solutions of *silicone* in forms of pulmonary edema caused by lung irritants (chlorine, etc.). Experiments in this direction, however, proved that antifoaming therapy is only moderately beneficial in this type of pulmonary edema. The effectiveness of silicone aerosol tends to support the opinion that the utility of alcohol vapor is not due to systemic effect, but rather to its effect on surface tension of the foam.

Several studies with antifoaming agents in clinical cases of pulmonary edema have been reported. At first, the tolerance for alcohol and the best method of administration were studied in normal volunteers as well as in cardiac patients without pulmonary edema. Two methods which gave excellent results are: (1) use of a face mask and a 20 to 30 per cent alcohol solution. This technique is especially suited for comatose patients; and (2) use of a nasal catheter and a 95 per cent alcohol solution. This method is to be preferred in conscious patients (Luisada et al., 1952).

In both methods, the alcohol is placed in the usual humidifier bottle, connected to an oxygen tank. The oxygen flow is kept at 2 to 3 liters/min for the first few minutes. Then, when the patient's mucosae become adapted to the irritant gas (local anesthesia?), the flow rate is gradually stepped up until, after 10 to 12 min, it reaches 9 or 10 liters/min, and is maintained at this level.[2]

By means of this technique, alcohol vapor was administered to 14 patients during 17 severe or extremely severe attacks of pulmonary edema. In 14 of the patients, previous conventional therapy had failed; in the other three, alcohol was the only therapy used. When oxygen-alcohol vapor was administered, the results were dramatically favorable in ten of the patients and definitely helpful in the other four.

It was noted that patients with severe attacks

[2] It should be emphasized that prolonged alcohol vapor treatment should be administered only by alternating periods of inhalation (30 to 40 min) with periods of rest (10 to 15 min) during which the patient is breathing air or oxygen. This prevents excessive absorption of alcohol which might lead to unwanted systemic effects.

responded most dramatically and that those with attacks of shorter duration had a more rapid recovery following alcohol vapor inhalation. Usually, subjective relief preceded objective improvement, so that the patient felt completely recovered even though some chest rales were still audible

The beneficial effects of alcohol vapor were also noted by Goldmann and Primiano in one obstetrical patient, by Gootnick and coworkers in two patients (one of them in shock), and by Weyl in seven surgical patients A further report summarized the results of alcohol therapy in 50 attacks (Goldmann and Luisada, 1952).

Another method was tried by Sadove: 12 per cent alcohol aerosol by face mask. His results were equally good.

Protracted pulmonary edema often starts suddenly but has a protracted course and is less likely to be a crucial issue for the prognosis Ten such cases, all of them in poor or terminal state, were submitted to alcohol vapor therapy, in spite of the fact that none was considered likely to survive Seven patients improved but the improvement was slower and less marked than in the acute attacks It was good in three, moderate in two, and minimal in two

Following these reports, alcohol vapor treatment of pulmonary edema was instituted in various hospitals It is unfortunate that, although the results are usually described as good, no other detailed clinical reports were published

The good results of another antifoaming agent, *2-ethylhexanol*, was stressed by Reich and associates, following its use in 14 unselected cases One-half of the patients showed a good response Other antifoaming agents are being tested by various investigators including Sadove

MANAGEMENT

Treatment of the Attack. At present, the directions for management of the attack are still tentative Further studies on the mechanism of action of the various drugs and physical procedures used in the different clinical types of pulmonary edema are necessary

Antifoaming therapy is compatible with any other drug or physical treatment Therefore, it is the viewpoint of the authors that, whenever possible, *all cases of pulmonary edema should be immediately treated with an antifoaming agent.* In cases of pulmonary edema due to inhalation of toxic gases, silicone aerosol may prove to be the agent of choice. While the patient is undergoing inhalation treatment, a thorough examination of the causes leading to the attack should be made, and their effects on the patient noted (pulse, blood pressure, electrocardiogram). After this routine examination, which may take from 20 to 30 min, and if the attack has not subsided, other procedures should be instituted.

Patients whose pulmonary edema is associated with hypertension or aortic insufficiency, stenosis, or coarctation, should receive 15 mg of *morphine*, and may also receive an intravenous injection of a *mercurial diuretic. Sympatholytic drugs* may be given but other hypotensive agents (e g, nitroglycerin, papaverine), having a milder action, may be preferred.

Cases with myocardial infarct and blood pressure above 100 (or above 120, if there was hypertension prior to the attack) should also receive 15 mg of *morphine*, 0 5 mg of *atropine* may be administered if there is marked bradycardia *Mercurial diuretics* may be given, but in small quantity (1 ml intravenously). If the blood pressure drops below 100 mm Hg, the dose of morphine should be not more than 10 mg, and no mercurial may be given. The same rationale applies to cases of rheumatic heart disease with mitral stenosis

Patients with cerebrovascular accidents should *not receive morphine* They may be given *atropine, mercurials*, and possibly, *chloral hydrate* by rectum or intravenously.

Morphine should be given only in small doses (5 mg) to patients who have inhaled toxic gases, even though it is beneficial.

Compression of the carotid sinus may be attempted in hypertensive patients.

Spinal anesthesia or *right stellate block* should be used only in cases of cerebrovascular accidents or hypertensive heart disease with protracted edema, which is refractory to treatment, and then only if blood pressure is high.

Venesection occasionally may be a lifesaving procedure It should be employed only in patients with hypertension, cerebrovascular accidents, mitral stenosis, or aortic insufficiency, who have high venous pressure or visible ve-

ing to break the cycle by acting on the foaming process itself was tried in the authors' laboratory. It was shown long ago (Laqueur and De Vries Reilingh) that large amounts of fluid may be present in the air passages with little danger to life; as soon as the surface tension of the fluid reaches a critical point, foaming starts. Cardiac catheterization in heart failure

PHILIP SAMET AND WILLIAM H. BERNSTEIN

Delineation of the varied *hemodynamic* patterns in congestive heart failure has been a natural consequence of the development of suitable techniques for catheterization of the right and left hearts and for determination of blood flow. Most data have been obtained via *right heart catheterization* by the peripheral venous route. *Left heart catheterization* has been approached by a variety of techniques, including transbronchial left atrial catheterization, posterior percutaneous left atrial puncture, direct anterior left ventricular puncture, retrograde arterial left ventricular catheterization, suprasternal left atrial puncture, left heart catheterization from the right heart via intracardiac openings, and transseptal left atrial puncture (Morrow, Braunwald, and Ross, 1960). The latter technique affords the most physiologic method of approach to the left heart. The *direct Fick principle* and the *indicator-dilution Stewart-Hamilton technique* have been utilized for determining cardiac output. Parameters of pressure, flow, and central blood volume have been evaluated either at rest or during exercise by the above techniques.

The normal pulmonary artery pressure at rest is below 30/10–15 mm Hg, systolic, diastolic and mean, respectively. Right ventricular pressure is normally less than 30/5, normal right atrial mean pressure is less than 6 mm Hg. Normal pulmonary artery wedge *pressure* is less than 13 mm Hg.

The zero level for these right heart pressures is 5 cm dorsal to the angle of Louis. In the authors' laboratory, the corresponding zero level for left heart pressures has been taken as 10 cm dorsal to the angle of Louis. Mean left atrial *pressure is then normally* less than 10 mm Hg.

Left ventricular *end-diastolic pressure* is normally less than 10 mm Hg.

Moderate *exercise*, producing a *100* to 200 per cent increment in oxygen consumption, results in an increase in right heart *pressures of* only a few millimeters of mercury. There is similarly little increase of left atrial mean and left ventricular end-diastolic pressures during exercise. Cardiac *output in the normal subject* at rest is *3.1 ± 0.4* liters/min/m². During exercise, the increase in output is related to the increment in oxygen consumption. The normal *exercise output increment* is 600 to 1,000 ml/100 ml increase in oxygen consumption.

Data for central, or so-called "pulmonary," blood volume are limited. In 76 normal subjects the pulmonary blood volume totaled 850 ml/m² B.S.A. (Lammerant, 1957). This value represents the total volume between the point of injection in the pulmonary artery and the sampling point in the systemic artery. The *true pulmonary blood volume* is the volume between the site of injection in the pulmonary artery and the sampling point in the left atrium. These data have been approached by separate determination of the pulmonary artery–systemic artery volume, and the left atrial–systemic artery volume. True pulmonary blood volume is the difference between these

nous engorgement. Its use in other cases is more questionable, even in the presence of venous engorgement. As an example, in patients with myocardial infarct and systemic venous congestion, venesection may precipitate shock.

Pressure respiration has, in general, a favorable effect in pulmonary edema. However, patients with cerebrovascular accidents and depression of the respiratory center may respond poorly to this treatment.

PROPHYLAXIS

It should be kept in mind that *transfusions of blood* and *infusions of plasma or saline strongly favor pulmonary edema*. Failure to consider this fact is responsible for many episodes of edema in medical and surgical wards. Moderation and wisdom in the administration of intravenous fluids may prevent many attacks, not only in cases with coronary or rheumatic heart diseases or anemia, but also in patients whose myocardium is less efficient because of anesthesia, surgical intervention, or infection.

Prevention of pulmonary edema in *hypertensive patients* can be obtained in two ways. (1) by decreasing the load placed upon the left ventricle (salt-poor diet, hypotensive drugs, sympathectomy, sedation), or (2) by stimulating the myocardium (digitalis glycosides). Both methods are extensively used. This may account for the impression that occurrence of pulmonary edema in these patients is less frequent than formerly.

Prevention of pulmonary edema in patients with *coronary* or *cerebrovascular diseases* is difficult; prevention of the arteriosclerotic process would be the answer. Central sedation, especially at night, may prolong the life of these patients.

Prevention of pulmonary edema in *rheumatic heart disease* is based on avoidance of excessive physical work, salt restriction, and use of diuretics and digitalization. Mitral valvotomy is effective in preventing attacks of pulmonary edema in patients with mitral block. In *acute rheumatic fever*, adrenocortical extracts are the best treatment whenever the myocardium is severely damaged. The same treatment may be lifesaving in *rheumatic heart disease with silent rheumatic carditis*.

Most of the other forms of pulmonary edema are caused by unpredictable and often unavoidable events. The incidence of pulmonary edema in these cases will be reduced following improvement of working conditions (decreased exposure to toxic materials), improvement of medical techniques (slow removal of serosal fluids, moderation in the administration of intravenous fluids, rational anesthesia), and improved therapy of infections, including those involving the heart or the nervous system.

Cardiac catheterization in heart failure

PHILIP SAMET AND WILLIAM H. BERNSTEIN

Delineation of the varied hemodynamic patterns in congestive heart failure has been a natural consequence of the development of suitable techniques for catheterization of the right and left hearts and for determination of blood flow. Most data have been obtained via *right heart catheterization* by the peripheral venous route. *Left heart catheterization* has been approached by a variety of techniques, including transbronchial left atrial catheterization, posterior percutaneous left atrial puncture, direct anterior left ventricular puncture, retrograde arterial left ventricular catheterization, suprasternal left atrial puncture, left heart catheterization from the right heart via intracardiac openings, and transseptal left atrial puncture (Morrow, Braunwald, and Ross, 1960). The latter technique affords the most physiologic method of approach to the left heart. The *direct Fick principle* and the *indicator-dilution Stewart-Hamilton technique* have been utilized for determining cardiac output. Parameters of pressure, flow, and central blood *volume* have been evaluated either at rest or during exercise by the above techniques.

The normal *pulmonary artery pressure* at rest is below 30/10–15 mm Hg, systolic, diastolic, and mean, respectively. Right ventricular pressure is normally less than 30/5, normal *right atrial* mean pressure is less than 6 mm Hg. Normal *pulmonary artery wedge pressure* is less than 13 mm Hg.

The zero level for these right heart pressures is 5 cm dorsal to the angle of Louis. In the authors' laboratory, the corresponding zero level for left heart pressures has been taken as 10 cm dorsal to the angle of Louis. Mean left atrial pressure is then normally less than 10 mm Hg.

Left ventricular *end-diastolic pressure* is normally less than 10 mm Hg.

Moderate *exercise*, producing a 100 to 200 per cent increment in oxygen consumption, results in an increase in right heart pressures of only a few millimeters of mercury. There is similarly little increase of left atrial mean and left ventricular end-diastolic pressures during exercise. Cardiac output in the normal subject at rest is 3.1 ± 0.4 liters/min/m². During exercise, the increase in output is related to the increment in oxygen consumption. The normal exercise output increment is 600 to 1,000 ml/100 ml increase in oxygen consumption.

Data for central, or so-called "pulmonary," blood *volume* are limited. In 78 normal subjects the pulmonary blood volume totaled 650 ml/m² B.S.A. (Lammerant, 1957). This value represents the total volume between the point of injection in the pulmonary artery and the sampling point in the systemic artery. The *true pulmonary blood volume* is the volume between the site of injection in the pulmonary artery and the sampling point in the left atrium. These data have been approached by separate determination of the pulmonary artery–systemic artery volume, and the left *atrial–systemic artery* volume. True pulmonary blood volume is the difference between these

two volumes (Dock et al., 1961; Milnor et al., 1960). Data for the true pulmonary blood volume in the normal subject determined by the pulmonary artery and left atrial injection techniques are as yet unavailable.

The development of *clinical congestive heart failure* is accompanied by alterations in intravascular and intracardiac pressure levels, in intracardiac pulse pressure contours, in cardiac output, and in total blood volume (or some segment thereof). *Left ventricular failure* is characterized by elevation of the left ventricular end-diastolic pressure; elevation of left atrial mean pressure necessarily follows. Pulmonary venous and arterial pressure will eventually increase. Cardiac output may be normal, increased, or decreased, depending on the cause of the heart failure. Arteriovenous difference is increased in *low-output failure* but may be normal or decreased in *high-output failure*. Right ventricular end-diastolic pressure may be normal at this stage, i.e., there may be a pure left-sided failure (Cournand, 1952). Subsequent elevation of right ventricular end-diastolic and right atrial mean pressure signifies the development of *combined heart failure*. On the other hand, in chronic pulmonary disease, right ventricular end-diastolic pressure may be elevated in the face of normal pulmonary artery wedge pressure, and therefore presumably normal left atrial mean and left ventricular end-diastolic pressures, i.e., there may be a pure right-sided failure.

These concepts emphasize the purely hemodynamic approach to heart failure without entering into a discussion of the clinical counterparts of heart failure. Indeed, hemodynamic evidence of heart failure may exist in the absence of clinical manifestations thereof (McCord et al, 1953, Musser et al., 1956). Most observers feel that such hemodynamic evidence, i.e., elevation of ventricular end-diastolic pressure, is sufficient to define the existence of heart failure. According to an opposing view, elevation of ventricular end-diastolic pressure may be due to marked thickening of the ventricular wall per se, with alteration of the distensibility characteristics of the ventricle. Elevation of ventricular end-diastolic pressure, from this viewpoint, would *not* be equated with the existence of congestive heart failure.

The introduction of exercise studies into cardiac catheterization procedures (Hickam and Cargill, 1948) has demonstrated that heart failure may be absent in the resting state but may readily develop during even moderate exercise—as defined by an elevation in ventricular end-diastolic pressure without an appropriate increase in cardiac output (Richards, 1949).

In summary, therefore, *the basic hemodynamic characteristics of congestive heart failure consist of an elevation of ventricular end-diastolic pressure.* Cardiac output may be low, normal or increased. Depression of the cardiac output without elevation of ventricular end-diastolic pressure does not constitute hemodynamic evidence of heart failure. The hemodynamic evidence of failure may become more evident during exercise studies or may appear only then. Ventricular end-diastolic pressure may further rise; cardiac output may rise only slightly, remain stationary, or even fall during exercise (Hickam and Cargill, 1948, Lewis et al., 1953).

Characteristic *changes in pulse pressure contours* may develop in the congested state. The atrial pressure curve may take on the characteristics seen in atrioventricular valvular insuffi-

[illegible]

of right atrial mean pressure and the development of *functional tricuspid insufficiency*. Typical, but not pathognomonic, alterations have been observed in the right atrial and right ventricular pressure curves of patients with *constrictive pericarditis*. The former curve has a distinct "W" form. The ventricular curve is character

pressure, [illegible]

a resultant small pulse pressure, and an *early diastolic dip*, down to a near-zero level (Bloomfield et al., 1946; Hansen et al, 1951; Harvey et al, 1953) (Fig 18-15). Similar pulse pressure contours have, however, also been observed in heart failure from other causes (Clark et al., 1956; Hetzl et al, 1953).

Emphasis has been placed on the mechanical aspects of cardiac function in heart failure. On the other hand, the role of the nervous system in the maintenance of systemic venous and pulmonary arterial hypertension in heart failure has been emphasized by Halmagyi (1952 and 1959).

Administration of dihydroergotamine to patients with chronic congestive heart failure (28 studies) 108

resulted in an increase in peripheral and central venous pressure in the absence of changes of systemic arterial pressure and cardiac output. A direct vasoconstrictor effect of dihydroergotamine on vascular smooth muscle was postulated as the cause of the rise in venous pressure. A number of drugs, including dihydroergotamine, Priscoline, Dibenamine, hexamethonium, morphine, reserpine, and acetylcholine, have been investigated for their potential vasomotor effect on the pulmonary circulation. Recent interest has centered on acetylcholine. Despite early promise, extensive intracardiac infusion of acetylcholine into the right heart in patients with mitral stenosis has failed to reveal a clinically significant consistent vasodilator effect at various levels of pulmonary hypertension (Samet et al, 1961, 1962).

Cardiac metabolism in the nonfailure and congestive heart failure states has received considerable attention (Olson, 1959, Danforth et al, 1960). The high-output failure seen in anemia and beriberi has been related to a defect in myocardial energy production caused by a reduced capacity for hydrogen transport. The more commonly encountered low-output failure of hypertensive and valvular heart disease is apparently related to a defect of the myosin component of actomyosin. It is quite likely that future advances in this field will result in *fruitful therapeutic advances.*

The hemodynamic patterns noted during cardiac catheterization in the commonly observed causes of heart failure will now be outlined

RHEUMATIC HEART DISEASE

The development of surgical therapy for rheumatic valvular heart disease has resulted in extensive studies of the hemodynamic status of subjects with this disease, both with and

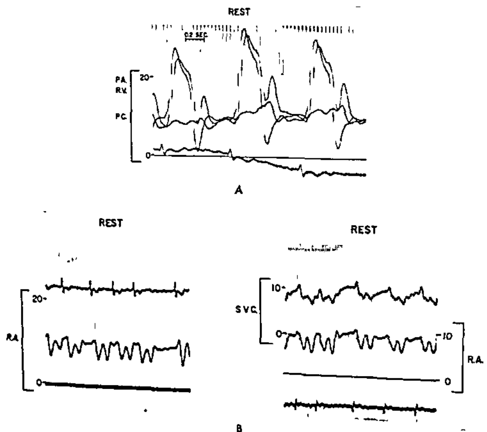

Fig 18-15. A. Pulmonary artery, right ventricular, and pulmonary artery wedge pressures in constrictive pericarditis. The diastolic dip on the right ventricular curve is to be noted. B Right atrial and superior vena cava curves in constrictive pericarditis The "W"-shaped curves are readily noted

without heart failure. The concept of *pure* left or right ventricular failure has been validated—elevation of left ventricular end-diastolic pressure with normal right ventricular end-diastolic pressure, as in aortic stenosis, or elevated right ventricular end-diastolic pressure in the face of normal left ventricular end-diastolic pressure, as in mitral stenosis.

Hemodynamic studies *during acute pulmonary edema* have revealed consistent changes.

Finlayson et al. (1961) studied 5 patients, 2 with pure mitral stenosis, 1 with mitral stenosis and systemic hypertension, 1 with mitral and aortic stenosis, and 1 with aortic regurgitation. The mean pulmonary artery pressures were 57, 76, and 37 mm Hg before, during, and after recovery from pulmonary edema. In 2 patients, mean pulmonary artery wedge pressure was 25 before pulmonary edema, this pressure rose to 39 mm Hg during pulmonary edema. Cardiac index changed little during pulmonary edema, but the heart rate rose from 101 to 122. In 2 patients, right ventricular end-diastolic pressure fell from 26 to 5 and from 15 to 4 mm Hg after recovery. Intravenous *hexamethonium* (6.5 to 25 mg) was given by cardiac catheter in 4 subjects and produced a rapid and dramatic clinical response. Fejfar et al (1959) studied 5 rheumatic patients under similar circumstances—4 with mitral stenosis and 1 with mitral insufficiency. The development of *dyspnea* was associated with a rise in pulmonary artery and pulmonary artery wedge pressure. Cardiac output fell only moderately. There did not appear to be a relationship between the degree of dyspnea and the decrease in output. Arterial oxygen saturation fell during pulmonary edema to as low as 60 per cent in 1 subject. Lenègre and Scébat (1952), as well as Hayward (1955), also recorded sharp increases in pulmonary artery and pulmonary artery wedge pressures during pulmonary edema. Little

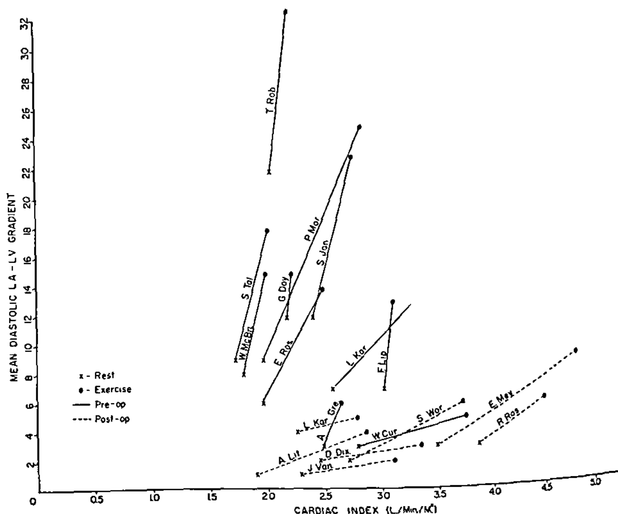

Fig. 18-16. Relationship between mitral diastolic gradient and the cardiac index in patients with mitral valve disease. The clear separation in the rate of change of gradient between the pre- and postoperative patients is apparent. W. Cur. is a possible example of the myocardial factor in mitral stenosis. A. Gre. is an asymptomatic woman with auscultatory evidence of mitral stenosis.

change in cardiac index was observed. These observations were made in subjects with pure mitral stenosis. Reductions of arterial oxygen saturation to levels as low as 45 per cent were observed. Gorlin et al. (1951) *made similar observations* in 8 patients with mitral stenosis studied at rest and in 3 such patients who developed pulmonary edema during exercise. All had pulmonary artery ... mm Hg. Cardiac index

... during pulmonary edema are not available at present, but limited observations at rest and during exercise are available in subjects with mitral stenosis not in pulmonary edema at *the time of study.* These data (Samet et al., 1959) show the expected sharp rise in left atrial mean pressure during exercise.

Comparison of patients before and after *mitral commissurotomy* revealed a marked difference in the rate of rise of left atrial pressure per unit increase of cardiac output during exercise (Fig. 18-16) The increase in left atrial pressure during *exercise is attributed to an increase* in both output and heart rate. The effect of the latter two parameters can be separated (Fig. 18-17) (*Silverman et al*, 1961). Comparison of left atrial and pulmonary artery wedge pressure revealed unexplained instances in which wide differences were observed *between these values* (*Bernstein et al*, 1960). Interesting artefacts in the recording of pulmonary artery wedge pressure were noted (*Fig* 18-18). These findings illustrate the potential hazards of drawing conclusions as to the level of left atrial pressure from the pulmonary artery wedge curve

Hemodynamic data are also available *in pure left heart failure of* rheumatic origin without clinically overt pulmonary *edema*

In 1 *subject* with mitral stenosis and insufficiency and aortic insufficiency (Harvey et al., 1949), studied *with* right heart catheterization, *control* cardiac index was moderately reduced (2 13 liters/min/m²), *and moderate pulmonary hypertension* was observed (58/31, 39) in the face of a normal right ventricular end-diastolic pressure, 3 mm Hg After digitalization, cardiac output and stroke volume rose 47 and 83 per cent, respectively Pulmonary artery pressure fell to normal levels Peripheral arterial resistance fell, and the heart rate decreased from 94 to 75 Yu et al. (1957) reported similar studies in 4 subjects with rheumatic heart disease—1 with aortic stenosis, 1 with predominant mitral insufficiency, and 2 with mitral

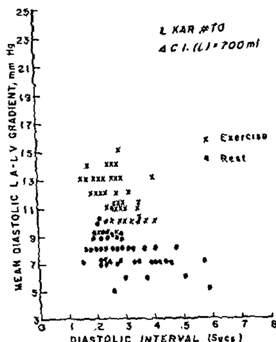

Fig. 18-17. Relationship between mitral diastolic gradient and the diastolic filling period at rest and during exercise. The increased exercise cardiac output results in larger exercise gradients at the same diastolic intervals as at rest.

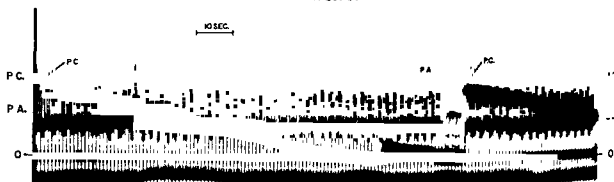
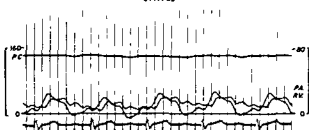


stenosis and insufficiency. Right ventricular end-*diastolic* pressure was normal. Control data revealed moderate to severe *elevation* of pulmonary artery mean and pulmonary artery *wedge mean* pressures. *Cardiac index* was markedly reduced in 2, slightly reduced in 1, and normal *in 1. Following digitalization* with *acetyl-strophanthidin*, the most consistent changes were *decreases* of pulmonary *artery* and pulmonary artery wedge pressures. Cardiac index rose *only minimally* in 3 subjects; an 18 per cent increase in output was *recorded in* the fourth *subject*

Failure of pulmonary artery pressures to return *to normal* levels following digitalization suggests the addition of mitral valve block, pulmonary vascular disease, *or* both to left heart *failure* as etiologic factors in pulmonary hypertension in these 4 subjects (Samet et al., 1958). The observed *fall* in pulmonary artery pressure *is*, however, highly suggestive of the coexistence of left heart failure. Harmanci et al. (1951) observed the acute effect of 1.5 *mg Cedilanid* given intravenously *in* 2 subjects with rheumatic heart disease, 1 with aortic stenosis, and 1 with *predominant* mitral *insufficiency*. *Control* right ventricular end-diastolic

pressure was normal. Moderate pulmonary hypertension was observed. *After digitalization,* pulmonary artery pressure again fell toward normal, but did not reach normal, and cardiac output rose. Similar studies of the effect of *acute digitalization in subjects with left heart* failure studied during combined right and left heart catheterization are not available as yet. However, Samet et al. (1959 and 1961) have made observations relative to heart failure during combined right and left heart catheterizations in patients with mitral and or aortic valve disease.



Pure right heart failure without left heart failure, i.e., a normal left ventricular end-diastolic pressure but elevated right ventricular end-diastolic pressure, has been observed in pure mitral stenosis. The converse, i.e., elevation of the left ventricular end-diastolic and *left atrial mean pressures without elevation of* the right ventricular end-diastolic pressure has been noted in patients with aortic stenosis, either at rest or during exercise. Elevation of left ventricular end-diastolic pressure to grossly abnormal levels (more than 20 mm Hg) has followed moderate exercise (doubling basal oxygen consumption) in subjects with rheumatic aortic stenosis. In one instance, left ventricular end-diastolic pressure rose to over 40 mm Hg (Fig. 18-19) without the development of clinical pulmonary edema or even dyspnea. Hancock and Fleming (1960) have also noted marked elevation of the left ventricular end-diastolic pressures in aortic stenosis; end-diastolic pressures as high as 48 mm Hg were observed in subjects studied at rest.

Fig. 18-18. A. Pulmonary artery wedge (p c) and pulmonary artery pressures. The progressive fall in wedge pressure is an unexplained artefact. B. Right ventricular, pulmonary artery, and wedge pressures with a triple-lumen catheter The wedge pressure (uppermost curve) has the contour of a delayed pulmonary artery curve. C. Marked artefacts in pulmonary artery wedge pressure (P A.W.) result in obviously false elevation of wedge pressures far above the pulmonary artery pressure.

Elevation of pulmonary artery pressure after digitalization in patients with rheumatic heart disease and mitral stenosis has been reported on occasion Greene et al. (1961) have discussed the interplay of the various factors that may result in such an elevation of pulmonary pressure. *Restriction of the pulmonary vascular bed and increase in cardiac output after digitalization are probably the underlying mechanisms in such instances.*

Any discussion of the effect of *digitalis* in patients with mitral valve disease raises the question of the myocardial factor. Harvey et al. (1955b) first described a group of patients with mitral stenosis in whom the clinical difficulties and physiologic abnormalities were postulated to stem from *myocardial insufficiency* These patients exhibited little or no pulmonary hypertension at rest, cardiac output was normal or depressed at rest but did not rise normally during exercise The latter characteristic separated these patients from those with the murmur of mitral stenosis but without *clinically significant* mitral valve block or myocardial insufficiency. Surgical intervention in the myocardial insufficiency group (Ferrer et al., 1955) was felt to be of little value Fleming and Wood (1959) stated that similar cases were observed in 3 2 per cent of 750 patients with rheumatic mitral valve disease Right heart catheterization revealed a low cardiac output at rest. Left atrial pressure was measured *only indirectly*—from pulmonary artery wedge pressure levels This indirectly determined mean left atrial pressure was only 7 mm Hg Fleming felt that mitral surgery did not improve the clinical status of these subjects. Soloff et al. (1957) have also described a similar group of subjects Underlying the concept of the myocardial factor in mitral stenosis is the thesis that the mean diastolic left atrial–left ventricular gradient would be minimal in these patients, both at rest and during exercise The demonstration of this minimal mitral diastolic gradient, or of its absence, has rarely been made during left heart catheterization (Samet et al., 1959) *Indeed surgically significant mitral stenosis has been observed in some sub-*

[illegible]

mitral stenosis, therefore, remains to be evaluated However, in one patient diagnosed after

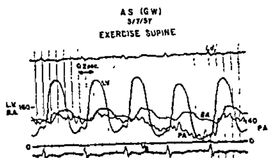

Fig. 18-19. Left ventricular, brachial artery, and pulmonary artery pressures during exercise in a patient with severe aortic stenosis. Left ventricular end-diastolic pressure is markedly elevated to over 40 mm Hg.

combined right and left heart catheterization, both right and left ventricular end-diastolic pressures were normal at rest but rose to abnormal levels during exercise despite a minimal mitral diastolic gradient at rest (4 mm Hg) and during exercise (7 mm Hg) (Samet et al., 1959).

Alternation of the pulse in either the lesser or greater circulation has been reported in catheterization studies in man Ferrer et al. (1956) recorded *alternation in the lesser circulation* in two patients with mitral valve disease; a third patient exhibited only systemic alternation. Cooper et al. (1958) noted *left ventricular alternation* in 15 of 28 patients with rheumatic aortic stenosis. *Alternation in the systemic arterial pulse* accompanied left ventricular alternation in all cases; the magnitude of the alternation was, however, greatly reduced in the systemic arterial pulse. In Cooper's study, *electrical alternans* was absent. Bernstein et al (1961) and Hancock and Fleming (1960) have also observed left ventricular alternation in aortic stenosis (Fig. 18-20).

In addition to the afore-mentioned right heart hemodynamic studies in acute heart failure and combined heart catheterization studies in mitral and aortic valve disease, a number of *enlightening studies* are available in patients with mitral stenosis employing right heart catheterization alone. Ferrer et al. (1952 and 1955) and Harvey (1955) have documented *the various causes of pulmonary hypertension in patients with mitral stenosis*, viz., mitral valve block, left heart failure, and pulmonary vascular disease. A decrease in pulmonary

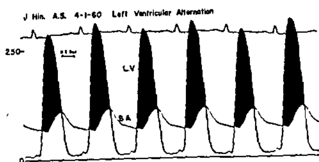

Fig. 18-20. Left ventricular pulsus alternans in severe aortic stenosis.

hypertension after digitalization pointed to *left heart failure* as at least a contributing factor to pulmonary hypertension. Gradual disappearance of pulmonary hypertension on repetitive right heart catheterization after mitral commissurotomy suggested *pulmonary vascular disease* as at least a contributing cause to elevation of pulmonary artery pressure. On the contrary, return of pulmonary artery pressure to normal levels immediately after mitral commissurotomy pointed to *mitral valve block* as the cause of pulmonary hypertension. The clinical picture of right heart failure was physiologically characterized by an elevation of the right ventricular end-diastolic pressure. Such elevation often developed during exercise, even when absent at rest. Cardiac index was usually diminished at rest and failed to increase normally during exercise.

The data of Samet et al. (1959) and Dickens et al. (1957) have clearly demonstrated that varying degrees of pulmonary hypertension may be associated with the same level of the mean diastolic left atrial–left ventricular gradient. Significant mitral valve block was found in the presence of normal, as well as elevated, pulmonary artery pressure. The presence of pulmonary hypertension cannot, therefore, be utilized as a measure of mitral valve block or as an indication for surgery

It should be emphasized that the significance of a mitral diastolic gradient must be interpreted with knowledge of the diastolic flow across the valve. A 5 mm Hg gradient flow with a cardiac index of 3 5 liters/min/m² connotes a valve size considerably different from one associated with the same gradient but with a cardiac index of 1.5 The hemodynamic evaluation of the effects of mitral commissurotomy is therefore difficult if right heart catheterization alone is employed, as by Donald et al. (1957)

Left heart catheterization is also of considerable value in the diagnosis of mitral stenosis in a select group of patients with very severe pulmonary hypertension; in these subjects, the murmur of mitral stenosis may be atypical in character or may even be absent. As described by Mackinnon et al. (1956), the physical signs are characteristic of severe pulmonary hypertension per se.

Cardiac catheterization techniques have been utilized to study coronary blood flow and myocardial oxygen consumption (Rowe et al, 1960). The results demonstrate a decrease in left ventricular coronary blood flow and a decrease in left ventricular oxygen consumption per unit weight of left ventricle.

Pulmonary blood volume, both total and true, as defined above, has been studied with cardiac catheterization techniques. Borden et al. (1949) first reported pulmonary artery to systemic artery volumes of 642 ml/m² in patients with rheumatic heart disease without signs of congestive heart failure. Lagerlof et al. (1949), Kopelman et al. (1951), Doyle et al. (1953), Rapaport et al. (1956), and Milnor et al. (1960) reported corresponding values ranging between 817 to 887 ml/m². These values are only slightly larger than those observed in normal subjects. True pulmonary blood volume, i.e., the volume between the pulmonary artery and the left atrium, has been determined by Milnor et al. (1960) and by Dock et al. (1961). These studies revealed true pulmonary blood volumes between 322 to 365 ml/m².

Physiologic studies by right and combined heart catheterizations in patients with rheumatic aortic stenosis have revealed that left ventricular failure with elevation of the end-diastolic pressure is not infrequently seen, as noted above. It is of considerable interest that the cardiac index has been found to be within normal limits, or even somewhat elevated, by both direct Fick and indicator-dilution techniques in patients with severe aortic stenosis with overt left ventricular failure (Hancock and Fleming, 1960; Dexter et al., 1958). Left heart catheterization has also revealed that many of the clinical features of aortic stenosis may be noted in symptomatic patients who are being considered for aortic commissurotomy—but significant aortic stenosis may not be present, as determined by the absence of a systolic left ventricular–systemic arterial gradient of any magnitude (Hancock et al, 1958).

Unnecessary cardiac surgery may thus be obviated.

ARTERIOSCLEROTIC HEART DISEASE

Hemodynamic data in *acute myocardial infarction* have become available in the past 10 years.

Freis et al. (1952) studied 11 patients with acute infarction. Cardiac output was measured by the *indicator-dilution technique*; T 1824 was injected via a polyethylene tube passed into an axillary or subclavian vein and was sampled from the femoral artery. Conditions of the patients were classified as (1) mild, (2) moderate and severe, and (3) with *cardiogenic shock*. The second group exhibited signs of congestive failure. The patients in the third group were severely ill, all eventually died. In the first group, cardiac index was normal—mean, 3.4 liters/min/m², heart rate, 92; stroke volume, 76 ml beat, and central venous pressure, 90 mm water. In the second group, cardiac index was 2.9 liters/min/m², heart rate, 101, stroke volume, 50, and central venous pressure, 120. In the third group, cardiac index was 1.8 liters/min/m², heart rate, 128, stroke volume, 27, and central venous pressure, 115. Central blood volume was similar in all three groups.

Gilbert et al. (1954) studied 20 patients with acute myocardial infarction by similar techniques. The first group (7 patients) exhibited neither heart failure nor shock, cardiac index was 2.61 liters/min/m², venous pressure was 130 mm water. The second group (6 subjects) was in cardiac failure, with an index of 1.9 liters/min/m² and a venous pressure of 167 mm water. All 7 subjects in the third group were in shock, with a cardiac index of 1.0 liters/min/m² and a venous pressure equal to 215 mm water.

Smith et al. (1954) made measurements of cardiac output in 9 patients with acute infarction without shock and in 6 with *shock*. Cardiac output was again measured by intravenous indicator injection with peripheral arterial sampling. In the patients without peripheral shock, cardiac index totaled 2.4 liters/min/m². After recovery, cardiac index increased significantly, to 2.7. In the 6 patients in shock, cardiac index was 1.65.

Gammill et al. (1955) investigated 37 patients with acute infarction. Cardiac output was determined by the indicator-dilution technique. Cardiac index was 4.25 liters/min/m² in the least severe group, 3.21 in the intermediate group, and 2.93 in the most severe group. On restudy 4 weeks after recovery, cardiac output in the third group had risen to the values in the first two groups. In those patients in shock, failure of peripheral vasomotor mechanism was not demonstrated.

Lee (1957) analyzed the data in 11 patients with acute infarction, utilizing similar techniques for determination of cardiac output. Cardiac index was normal, 3.7 liters/min/m², even in those patients in shock. The most consistent hemodynamic observation in these patients was an *elevated venous pressure*.

Broch et al. (1959) studied 35 subjects with acute myocardial infarction. Those in group I (18 subjects) were uncomplicated, those in group II exhibited shock or failure. *Indicator-dilution techniques* with peripheral venous injection were employed. The cardiac index in the first group was normal, 3.03 liters/min/m², this index was reduced to 2.04 in the second group. Stroke volume changes followed output data. Eight patients in group II died, 9 survived. The cardiac index in those that survived was 2.36; in the nonsurvivors the index was 1.73. On restudy 3 weeks after infarction, the patients in group I exhibited little change, while those in group II showed considerable improvement.

Cardiac dynamics in asymptomatic male patients with *healed myocardial infarction* were studied by Chapman and Fraser (1954). The infarcts had occurred at least 6 months before study. The cardiac index at rest was 2.95 liters/min/m². The increase in cardiac output during exercise was equivalent to that noted in a comparable group of normal subjects, indicating that a normal response to the stress of exercise could be expected in this type of subject.

Lewis et al. (1953) catheterized three patients with arteriosclerotic heart disease and heart failure. Cardiac index at rest averaged 1.73 liters/min/m². Stroke volume per square meter averaged 21 ml. Pulmonary artery wedge pressure (employed as an indicator of mean left atrial pressure) was 32 mm Hg. Pulmonary artery mean pressure was 44 mm Hg. During moderate exercise (oxygen consumption rose from 133 to 198 ml/min/m²), cardiac index rose to 1.9 liters/min/m², stroke index fell to 19 ml. Pulmonary artery wedge pressure rose to 39 mm Hg; pulmonary artery mean pressure increased to 57 mm Hg. Right atrial mean pressure data, obtained only at rest, averaged 18 mm Hg, indicating that right as well as left heart failure was present.

Bloomfield et al. (1948) studied the effect of intravenous *ouabain* in three patients with arteriosclerotic heart disease in *failure*. Control measurements revealed pulmonary hypertension with systolic pulmonary artery pressures ranging between 60 to 80 mm Hg. Right ventricular end-diastolic pressures were about 20 mm Hg. Cardiac index averaged 1.33 liters/min/m². Intravenous ouabain resulted in little change in right ventricular end-diastolic pressure. Systolic, diastolic, and mean pul-

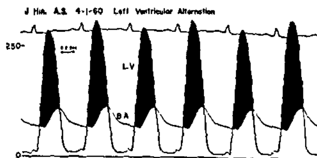

Fig. 18-20. Left ventricular pulsus alternans in severe aortic stenosis.

hypertension after digitalization pointed to *left heart failure* as at least a contributing factor to pulmonary hypertension. Gradual disappearance of pulmonary hypertension on repetitive right heart catheterization after mitral commissurotomy suggested *pulmonary vascular disease* as at least a contributing cause to elevation of pulmonary artery pressure. On the contrary, return of pulmonary artery pressure to normal levels immediately after mitral commissurotomy pointed to *mitral valve block* as the cause of pulmonary hypertension. The clinical picture of right heart failure was physiologically characterized by an elevation of the right ventricular end-diastolic pressure. Such elevation often developed during exercise, even when absent at rest. Cardiac index was usually diminished at rest and failed to increase normally during exercise.

The data of Samet et al. (1959) and Dickens et al (1957) have clearly demonstrated that varying degrees of pulmonary hypertension may be associated with the same level of the mean diastolic left atrial–left ventricular gradient. Significant mitral valve block was found in the presence of normal, as well as elevated, pulmonary artery pressure The presence of pulmonary hypertension cannot, therefore, be utilized as a measure of mitral valve block or as an indication for surgery

It should be emphasized that the significance of a mitral diastolic gradient must be interpreted with knowledge of the diastolic flow across the valve A 5 mm Hg gradient flow with a cardiac index of 3.5 liters/min/m² connotes a valve size considerably different from one associated with the same gradient but with a cardiac index of 1 5 The hemodynamic evaluation of the effects of mitral commissurotomy is therefore difficult if right heart catheterization alone is employed, as by Donald et al. (1957)

Left heart catheterization is also of considerable value in the diagnosis of mitral stenosis in a select group of patients with very severe pulmonary hypertension; in these subjects, the murmur of mitral stenosis may be atypical in character or may even be absent. As described by Mackinnon et al. (1956), the physical signs are characteristic of severe pulmonary hypertension per se.

Cardiac catheterization techniques have been utilized to study coronary blood flow and myocardial oxygen consumption (Rowe et al, 1960). The results demonstrate a decrease in left ventricular coronary blood flow and a decrease in left ventricular oxygen consumption per unit weight of left ventricle.

Pulmonary blood volume, both total and true, as defined above, has been studied with cardiac catheterization techniques. Borden et al. (1949) first reported pulmonary artery to systemic artery volumes of 642 ml/m² in patients with rheumatic heart disease without signs of congestive heart failure. Lagerlof et al. (1949), Kopelman et al (1951), Doyle et al. (1953), Rapaport et al. (1956), and Milnor et al. (1960) reported corresponding values ranging between 817 to 887 ml/m². These values are only slightly larger than those observed in normal subjects. True *pulmonary* blood volume, i.e., the volume between the pulmonary artery and the left atrium, has been determined by Milnor et al. (1960) and by Dock et al. (1961). These studies revealed true pulmonary blood volumes between 322 to 365 ml/m².

Physiologic studies by right and combined heart catheterizations in patients with rheumatic aortic stenosis have revealed that left ventricular failure with elevation of the end-diastolic pressure is not infrequently seen, as noted above. It is of considerable interest that the cardiac index has been found to be within normal limits, or even somewhat elevated, by both direct Fick and indicator-dilution techniques in patients with severe aortic stenosis with overt left ventricular failure (Hancock and Fleming, 1960, Dexter et al., 1958). Left heart catheterization has also revealed that many of the clinical features of aortic stenosis may be noted in symptomatic patients who are being considered for aortic commissurotomy—but significant aortic stenosis may not be present, as determined by the absence of a systolic left ventricular–systemic arterial gradient of any magnitude (Hancock et al, 1958).

Unnecessary cardiac surgery may thus be obviated.

ARTERIOSCLEROTIC HEART DISEASE

Hemodynamic data in *acute myocardial infarction* have become available in the past 10 years

Freis et al. (1952) studied 11 patients with acute infarction *Cardiac output was measured by the indicator-dilution technique*, T 1824 was injected via a polyethylene tube passed into an axillary or subclavian vein and was sampled from the femoral artery Conditions of the patients were classified as (1) mild, (2) moderate and severe, and (3) with *cardiogenic shock* The second group exhibited signs of congestive failure The patients in the third group were severely ill, all eventually died In the first group, cardiac index was normal—mean, 3 4 liters/min/m², heart rate, 92, stroke volume, 76 ml beat, and central venous pressure, 90 mm water In the second group, cardiac index was 2 9 liters/min/m², heart rate, 101, stroke volume, 50, and central venous pressure, 120. In the third group, cardiac index was 1 8 liters/min/m², heart rate, 128, stroke volume, 27, and central venous pressure, 115. Central blood volume was similar in all three groups

Gilbert et al (1954) studied 20 patients with acute myocardial infarction by similar techniques. The first group (7 patients) exhibited neither heart failure nor shock, cardiac index was 2 61 liters/min/m², venous pressure was 130 mm water. The second group (6 subjects) was in cardiac failure, with an index of 1 9 liters/min/m² and a venous pressure of 167 mm water. All 7 subjects in the third group were *in shock, with a cardiac index* of 1 0 liters/min/m² and a venous pressure equal to 215 mm water

Smith et al (1954) made measurements of cardiac output in 9 patients with acute infarction without shock and in 6 *with shock Cardiac output* was again measured by intravenous indicator injection with peripheral arterial sampling In the patients without peripheral shock, cardiac index totaled 2 4 liters/min/m² After recovery, cardiac index increased significantly, *to 2 7. In the 6 patients* in shock, cardiac index was 1 65.

Gammill et al (1955) investigated 37 patients with acute infarction Cardiac output was determined by the *indicator-dilution technique* Cardiac index was 4 25 liters/min/m² in the *least severe* group, 3.21 in the intermediate group, and 2.93 in the most severe group. On restudy 4 weeks after recovery, cardiac output in the third group had risen to the values in the first two groups In those patients in shock, failure of peripheral vasomotor mechanism was not demonstrated

Lee (1957) analyzed *the data in* 11 patients with acute infarction, utilizing similar techniques for determination of cardiac output. Cardiac index was normal, 3.7 liters/min/m², even in those patients in *shock*. The most consistent hemodynamic observation in these patients was an *elevated venous pressure*.

Broch et al. (1959) studied 35 subjects with acute myocardial infarction. Those in group I (18 subjects) were uncomplicated, those in group II exhibited shock or failure. *Indicator-dilution techniques* with peripheral venous injection were employed The cardiac index *in the first group* was normal, 3 03 liters/min/m², this index was reduced to 2.04 in the second group Stroke volume changes followed output data. Eight patients in group II died, 9 survived The cardiac index in those that survived was 2.36, in the nonsurvivors *the index* was 1.73 On restudy 3 weeks after infarction, the *patients in group I exhibited* little change, while those in group II showed considerable improvement.

Cardiac dynamics in asymptomatic male patients with *healed myocardial infarction* were studied by *Chapman and Fraser (1954). The infarcts had* occurred at least 6 months before study. The cardiac index at rest was 2 95 liters/min/m². The increase in cardiac output during exercise was equivalent to that noted in a comparable group of normal subjects, indicating that a normal response to the stress of exercise could be expected in this type of subject

Lewis et al. (1953) catheterized three patients with arteriosclerotic heart disease and heart failure. Cardiac index at rest averaged 1.73 liters/min/m². Stroke volume per square meter averaged 21 ml. *Pulmonary artery wedge pressure (employed as an* indicator of mean left atrial pressure) was 32 mm Hg Pulmonary artery mean pressure was 44 mm Hg During moderate exercise (oxygen consumption rose from 133 to 198 ml/min/m²), cardiac *index rose to 1.9 liters/min/m²*; stroke index fell to 19 ml Pulmonary artery wedge pressure rose to 39 mm Hg, pulmonary artery mean pressure increased to 57 mm Hg Right atrial mean pressure data, obtained only at rest, averaged 18 mm Hg, *indicating that right as well as left heart failure* was present.

Bloomfield et al (1948) studied the effect of intravenous *ouabain* in three patients with arteriosclerotic heart disease in failure. Control *measurements revealed* pulmonary hypertension with systolic pulmonary artery pressures ranging between 60 to 80 mm Hg. Right ventricular *end-diastolic* pressures were about 20 mm Hg Cardiac index averaged 1.33 liters/min/m² Intravenous ouabain *resulted in little* change in right ventricular end-diastolic pressure. Systolic, diastolic, and mean pul-

monary artery pressures rose within 1 hr. Cardiac output rose to about 2.1 liters/min/m². These responses are compatible with the effect of increased flow upon a restricted pulmonary bed. Judson et al. (1955a) catheterized two patients with arteriosclerotic heart disease, one in failure, one in cardiac compensation. In the latter subject, right ventricular end-diastolic pressures remained normal at rest and during exercise; pulmonary artery wedge pressure was elevated only during exercise, suggesting the development of left heart failure. Cardiac index was diminished at rest (1.95 liters/min/m²) and rose subnormally (relative to the increase in oxygen consumption) during exercise. The minimal pulmonary hypertension at rest rose markedly during exercise. In the decompensated subject, right ventricular end-diastolic pressure was markedly elevated at rest and rose further during exercise. Moderately severe pulmonary hypertension was observed at rest and rose further during exercise. The cardiac index at rest was 2.10 and rose subnormally during exercise

Hemodynamic studies during episodes of *precordial pain* have been reported by Muller and Rorvik (1958) Eleven subjects had previous myocardial infarction; precordial pain was the predominant symptom. Observations at rest showed elevation of the pulmonary artery wedge pressure in only 1 subject. Mean pulmonary artery pressure was minimally elevated in 3 subjects; cardiac index was normal During *bicycle exercise* in the recumbent position, 7 of 8 patients developed precordial pain Exercise elevations in mean pulmonary artery and wedge pressures were common. Cardiac output rose normally during exercise Three patients with pain but without recognized infarction were investigated Normal resting hemodynamics were noted, during exercise, significant increments in wedge and pulmonary artery pressures were observed Two patients developed spontaneous precordial pain during catheterization. Control hemodynamics were normal During the episode of pain, marked elevation of wedge pressure occurred. Eight patients complained of *exertional dyspnea* without pain. Cardiac enlargement was present in all, cardiac index was normal in 6 Pulmonary artery and wedge pressures were elevated at rest and rose further during exercise In 4 additional patients, *nitroglycerin* administration prevented an exercise elevation in pulmonary artery wedge pressure.

Gorlin et al. (1959a) and Brachfeld et al (1959) investigated the action of *nitroglycerin* on the coronary circulation and on right and left heart hemodynamics. In normal subjects and in those with "mild" cardiac disease (with a small atrial defect and a grade 1 basal diastolic murmur), nitroglycerin caused no change in cardiac output, and pulmonary artery and wedge pressures fell slightly. Brachial artery pressure decreased minimally. Coronary artery blood flow and oxygen consumption per 100 Gm of left ventricular muscle increased 63 per cent after administration of *nitroglycerin*. On the other hand, in patients with coronary artery disease or increased left ventricular work (mitral insufficiency, aortic valve disease, or both), nitroglycerin administration resulted in a 15 per cent fall in cardiac index. Brachial artery, pulmonary artery, and pulmonary artery wedge pressure fell 15, 50, and 50 per cent, respectively. Coronary blood flow and oxygen consumption either fell slightly or remained unchanged. A concept of "fixed" coronary blood flow was suggested to explain the latter results in patients with coronary artery disease and increased left ventricular work.

Selzer (1959 and 1960) has investigated the hemodynamic consequences of arteriosclerotic heart disease after therapy for, and recovery from, clinical left heart failure. Left atrial mean pressure was measured as mean pulmonary artery wedge pressure The conditions of the patients studied fell into four categories (1) normal resting dynamics with *abnormal* response to exercise, i.e., the *development of* pulmonary artery hypertension during exercise, (2) normal resting left atrial pressure with a low resting cardiac output, (3) elevated left atrial pressure with a normal cardiac output at rest, (4) elevated left atrial and pulmonary artery mean pressures and a low cardiac output at rest. Marked similarities and only minor differences were observed between the hemodynamic changes caused by elevation of the left atrial pressure in mitral stenosis and those caused by chronic left ventricular failure.

Sobol et al (1959) evaluated the effect of induced peripheral vasodilatation (with *Arfonad*) in 4 patients with arteriosclerotic heart disease in failure Control data revealed marked reduction in cardiac index with elevation of pulmonary artery and wedge pressure and right ventricular end-diastolic pressure. Peripheral vasodilatation resulted in an increase in cardiac index with a decrease in pulmonary artery and right ventricular pressures.

... (1960) and Eisenberg et

...

to moderate heart failure, cerebral blood flow and oxygen consumption were normal despite a significant increase in cerebral vascular resistance. In severe heart failure, cerebral blood flow and oxygen consumption were both significantly decreased. In advanced heart failure in confused subjects, further marked decreases were observed in the latter two parameters.

HYPERTENSIVE HEART DISEASE

The development of effective depressor therapy for essential hypertension has led to detailed hemodynamic studies in patients with this disease. Cardiac index and right heart pressures are normal in the patient not in failure (Varnauskas, 1955; Goldring and Chasis, 1944). Left heart catheterization data are not available. Ganglionic-blocking agents, guanethidine, and bretylium, all produced decrease in cardiac output as part of the hypotensive mechanism noted with these agents. Chlorothiazide administration also results in a decrease in cardiac output during initiation of therapy (Conway and Lauwers, 1960; Crosley et al., 1958; Dustan et al., 1959). Conway and Lauwers (1960) have shown, however, that more prolonged chlorothiazide administration is not associated with a reduction in output.

Hemodynamic data in left ventricular failure have been reported. Werko and Lagerlof (1949) were the first to report elevation of pulmonary artery wedge pressure in hypertensive subjects, suggesting left heart failure. Harvey et al. (1949) reported 3 patients with pure left ventricular failure secondary to systemic arterial hypertension. Pulmonary artery pressure was elevated in all 3; right ventricular end-diastolic pressures were normal. Cardiac index was normal in 1, low normal in 1, and reduced in the third. After administration of

...

changed. These studies demonstrated that the initial action of digoxin was directly exerted on ...

... upon the enlarged hypertensive heart of 2 patients not in failure at the time of study.

Right ventricular end-diastolic pressure remained unchanged, but cardiac index fell significantly. The decreases in output in 3 subjects with arteriosclerotic heart disease not in failure were of lesser magnitude.

Johnson et al. (1957) catheterized 6 patients with hypertensive heart disease and right and left heart failure before and after sublingual nitroglycerin administration. The control elevated mean pulmonary artery pressure fell 10 mm Hg; a simultaneous fall in systemic arterial pressure was observed. No correlation could be established between the decreases of pressure in the two arterial trees. In two instances, pulmonary artery wedge pressure was also measured; this value was elevated and fell after nitroglycerin administration, suggesting a decrease in left atrial pressure. Cardiac output data were not available. The mechanism of the fall in pulmonary artery pressure is, therefore, not clear.

Ferrer et al. (1960) reported studies in subjects with hypertensive heart disease suffering from right and left heart failure. Four patients had sinus rhythm. Control measurements revealed low cardiac indexes, moderate to severe pulmonary hypertension, and elevation of right ventricular end-diastolic pressure. Intracardiac digoxin resulted in a rise of cardiac index, and a fall of pulmonary artery and right ventricular pressures. In one patient, the increase of cardiac output was associated with a rise of pulmonary artery pulse pressure. In two patients, the rhythm was atrial fibrillation. Digitalization resulted in hemodynamic changes similar to those observed in patients with sinus rhythm. The control data in the patients with atrial fibrillation revealed more marked reduction of cardiac index and considerably less pulmonary hypertension than in those with sinus rhythm.

Detailed analysis of the interrelationships between the varied hemodynamic responses to acute digitalization, i.e., changes in heart rate, cardiac output, and right heart pressures, revealed that changes in these parameters did not necessarily occur simultaneously. Increments in cardiac index could precede changes in right heart pressures or vice versa. No constant relationship could be established between a fall in heart rate and alterations of right heart pressure or changes of cardiac index.

The data in this study thus emphasize the concept that digitalization may result in clinical and hemodynamic improvement without

immediate rate changes. The implication of this concept in the clinical use of digitalis is obvious. The results of Ferrer's study also illustrate that *significant clinical and hemodynamic improvement may follow relatively small doses of digoxin.* Results of similar studies in which left atrial and left ventricular pressure data are also available will be awaited with great interest. These hemodynamic alterations following digitalization in patients with hypertensive heart disease were also observed in patients in combined right and left heart failure caused by arteriosclerotic heart disease.

The catheterization studies in patients in heart failure by Bloomfield et al (1948), Lewis et al. (1953), Selzer (1959), Selzer and McCaughey (1960), and Sobol, Eichna, et al. (1959) also included persons with hypertensive heart disease. The results were similar to those noted in patients with arteriosclerotic heart disease in failure.

Judson *et al* (1955b) investigated the hemodynamic effects of *venous congestion* or of *phlebotomy* in patients with hypertensive heart disease with and without heart failure.

Cardiac index data are not available. In the 3 subjects not in failure, right heart pressures were normal. After venous congestion, cardiac output fell more than 10 per cent Right heart pressures were unchanged. In the 4 subjects in heart failure, moderate to severe pulmonary artery hypertension was recorded with elevation of the right ventricular end-diastolic pressure. Venous congestion in three subjects resulted in a slight increase in cardiac output and a fall in right ventricular end-diastolic pressure and pulmonary artery pressure. Phlebotomy produced a similar result in the fourth subject.

Donald (1959a) and Taylor (1957) reported data on circulatory studies in hypertensive patients studied at rest and during exercise.

Twenty subjects were studied Thirteen subjects in group I were free of marked left ventricular enlargement or dyspnea Seven subjects in group II had severe exertional dyspnea. The patients in group I exhibited normal cardiac indexes and pulmonary artery and wedge pressures at rest. During exercise, cardiac output rose normally, but an increase in wedge pressure was commonly observed. In group II, cardiac indexes were often but not invariably decreased at rest. Wedge pressures were elevated in some instances but not in all. During exercise, all patients in group II showed an impairment of the cardiac output response and a rise of wedge pressure. It is of considerable interest that the electrocardiographic demonstration of left ventricular hypertrophy did not necessarily imply hemodynamic abnormality. A number of patients with this electrocardiographic pattern showed normal hemodynamics both at rest and during exercise. One patient with a normal electrocardiogram, on the other hand, exhibited abnormal hemodynamic data.

COR PULMONALE

Hemodynamic studies in cor pulmonale (heart disease secondary to diseases of the lung) with and without congestive heart failure have provided considerable background of the pathophysiology of this disease. A lively discussion has ensued as to the cardiac output in cor pulmonale due to obstructive pulmonary emphysema. Several authors have reported that *the cardiac index in obstructive pulmonary emphysema with cor pulmonale is higher than in patients with valvular, hypertensive, or arteriosclerotic heart disease, and may be normal or even higher than normal.* However, other studies have presented conflicting results, in that *the cardiac index was normal or decreased in these patient*

attempted to

out that the

normal in chronic cor pulmonale secondary to *obstructive emphysema*—at least in Mounsey's series. The high cardiac index noted in Mounsey's patients was *secondary* to the high resting oxygen consumption. The normal arteriovenous difference in these patients was contrasted with the lower-than-normal arteriovenous difference observed in the high-output failure of severe anemia and systemic arteriovenous fistula.

Other investigators have tried to relate the level of cardiac output to the arterial oxygen saturation. Arterial hypoxemia has been postulated to be at least one of the mechanisms of the elevated cardiac index observed in some subjects Whatever the initial level of cardiac output in patients with cor pulmonale due to emphysema in heart failure, there is considerable evidence that as such patients recover from failure, a decrease in output takes place.

Coronary blood flow in pulmonary emphysema and cor pulmonale (Rose et al., 1956) 113

is within the normal range. In one patient with an elevated cardiac index, coronary blood flow was also elevated.

Cor pulmonale due to obstructive *emphysema is often associated with some degree of pulmonary hypertension*, either at rest or during exercise Arterial oxygen unsaturation below 80 per cent, hypercarbia, increased cardiac index, increased total blood volume, and restriction of the *pulmonary vascular bed, either* structural or vasoconstrictive, are some of the factors that have been suggested as causing or contributing to pulmonary hypertension (Fishman and Richards, 1956, McMichael, 1959).

Slight to moderate pulmonary hypertension with elevation of right ventricular end-diastolic pressure is commonly observed in the decompensated state Acute digitalization results in *an increase of cardiac output and a decrease of right ventricular end-diastolic pressure,* but in contrast to the findings in pure left ventricular failure, *a further rise developed in pulmonary artery pressure.* The increase of pulmonary artery pressure under such circumstances is probably due to the effect of an increase of cardiac output in the presence of a restricted pulmonary vascular bed Restudy weeks to months after the first catheterization revealed marked decrease of pulmonary artery pressure to normal or slightly elevated levels, right ventricular end-diastolic pressure had returned to normal *Of considerable interest* was the decrease of cardiac output at this time compared to the acute studies in heart failure (Ferrer et al, 1950, Özcan et al, 1951). Digitalization in patients with obstructive emphysema *not in failure* produced none of these changes.

Exercise studies in obstructive emphysema, with or without cor pulmonale, usually show elevation of pulmonary artery pressure if it was initially normal, or a further elevation if it was initially *elevated*. Cardiac output data are limited (Ferrer and Harvey, 1959, Hickam and Cargill, 1948) In some instances, blood flow rises normally during exercise with a rise in right ventricular end-diastolic pressure, in more severe cases, there is little or no rise in output despite a further *increase in right* ventricular end-diastolic pressure.

Kyphoscoliosis may also be associated with cor pulmonale and heart failure (Bergofsky et al., 1959, Fishman et al, 1956a)

Cardiac index was normal in 13 patients with kyphoscoliosis at rest. None was in *failure. Pulmonary hypertension was present* in 5 subjects at *rest* During exercise, abnormal increments were observed in pulmonary artery pressure in all instances. The exercise increase of cardiac index was normal.

The mechanism of cor pulmonale in these subjects is *chest deformity resulting in an increased work of breathing, alveolar hypoventilation, hypercapnea, hypoxemia, and pulmonary hypertension.* In the above forms of cor pulmonale, pulmonary artery wedge pressure is normal both at rest and during exercise, indicating that pulmonary artery hypertension is caused by increased resistance to flow in the pulmonary vascular bed at a point proximal to the left atrium.

Unlike the findings in cor pulmonale with obstructive emphysema, cardiovascular dynamics in patients with *diffusion block* (Harvey et al., 1951b) are characterized by pulmonary hypertension at rest and a considerable increase in cardiac index (mean, 3.99 liters/min/m²) in the presence of a normal hematocrit. Pulmo*nary hypertension may be present before* significant hypoxemia develops at rest. In these subjects, pulmonary hypertension appears to be caused by anatomic restriction of the vascular bed, rather than by the diverse physiologic factors operative in pulmonary emphysema.

Demonstration of the enlargement of the *bronchial arterial tree in bronchiectasis* (Liebow et al., 1949) has aroused interest in measurement of the bronchial arterial flow by simultaneous estimation of right and left ventricular outputs (Cudkowicz et al, 1959, Nakamura et al., 1961) and by simultaneous cardiac *catheterization*, bronchospirometry, and unilateral *pulmonary artery occlusion* (*Fishman* et al, 1958).

CONSTRICTIVE PERICARDITIS

Some of the varied hemodynamic patterns *that develop in* pericardial disease have been outlined by *Harvey et al. (1953)* Mechanical and myocardial factors in *chronic constrictive* pericarditis were differentiated.

One patient of Harvey's series presented the classic clinical and hemodynamic patterns of *constrictive* pericarditis. Mild pulmonary *hypertension was present*, with a narrowed pulse pressure, *systolic pulmonary* artery pressure was only minimally elevated in the face

of disproportionate elevation of the diastolic and mean pulmonary artery pressures. Right ventricular end-diastolic pressure was markedly elevated, with the typical early-diastolic dip rising to a diastolic plateau (Fig. 18-15). Cardiac index was slightly reduced. These hemodynamic abnormalities, due predominantly to a thickened, poorly distensible pericardium, had completely disappeared 3 months after surgery. A second patient exhibited the same classic hemodynamic findings of constrictive pericarditis but had a normal cardiac index in the absence of clinical signs or symptoms of this disease. A third patient demonstrated that extensive *pericardial calcification* may exist in the absence of hemodynamic or clinical cardiac abnormalities, at least at rest. The fourth subject exhibited a marked reduction in cardiac index, associated with a narrowed pulmonary artery pulse pressure, a high diastolic pressure, and a slightly elevated systolic pressure. Right ventricular end-diastolic pressure was markedly elevated. After acute digitalization during catheterization, cardiac output rose, with a fall in pulmonary artery and right ventricular pressures. This response suggested a failing myocardium in this patient with constrictive pericarditis. The fifth subject showed a normal cardiac output but with right ventricular and pulmonary artery pressure curves characteristic of constrictive pericarditis. After 1 month of intensive therapy, restudy revealed considerable diminution of the hemodynamic signs of constrictive pericarditis. These alterations rendered the concept of the mechanical interference of pericardial constriction per se untenable. The pathogenesis of the hemodynamic abnormalities in this last case remained unclear.

Hansen et al. (1951) have published similar data illustrating the typical *early-diastolic dip* in the right atrial and ventricular curves. These dips disappeared after pericardiectomy. Murphy et al. (1958) studied 6 patients with *constrictive pericarditis*. Cardiac indexes varied from markedly reduced levels to normal levels. Right atrial and right ventricular end-diastolic pressures were typically elevated, as were pulmonary artery pressures. Pulmonary artery wedge pressures were also increased. On exercise, further increases were noted in right heart pressures. In 3 cases, right heart pressures were normal during rest and exercise after surgery.

Wilson et al. (1954) have reported similar data in 10 patients with constrictive pericarditis. A right ventricular diastolic dip was present in all patients, together with marked elevation of the right ventricular end-diastolic pressure. A small pulmonary artery pulse pressure was noted. Identical hemodynamic abnormalities were observed in 3 patients with *pericardial effusion*. Wilson stated that the right ventricular diastolic to systolic pressure ratio was greater than 40 per cent in constrictive pericarditis.

It must be emphasized that although the above hemodynamic abnormalities are highly characteristic of constrictive pericarditis, they are not pathognomonic thereof. Balchum et al. (1956) and Clark et al. (1956) have emphasized that patients with *endocardial fibrosis* and *nonspecific myocarditis* may exhibit identical abnormalities.

HIGH-OUTPUT FAILURE

Cardiac failure associated with the high-output state has evoked considerable interest. Most cases have been associated with systemic arteriovenous fistulas, anemia, beriberi, and hyperthyroidism. Reduced resistance to outflow of blood from the systemic arterial tree is common to these conditions (Youmans, 1957).

Gorlin et al. (1959b) have described a group of 8 subjects with a persistently elevated *cardiac output* associated with cardiac *hypertrophy* and a precordial systolic murmur. The average cardiac index was 6.4 liters/min/m². The average oxygen consumption was 177 ml/min/m², a figure considerably higher than the basal level of about 125 to 135 ml/min/m². The arteriovenous difference was 2.8 vol per cent, a figure comparable to the levels seen in anemia and systemic fistulas with failure. The resting heart rate of 79 suggests that anxiety was not the cause of the elevation in cardiac output. The stroke index was therefore *increased* to 80 ml/beat/m². The response to exercise was unusual, however, in that *cardiac output* remained unchanged despite an increase in oxygen consumption. The etiology of these unusual hemodynamic findings is uncertain.

Perhaps the most typical example of *high-output failure* is seen in patients *with systemic arteriovenous fistulas*.

Cardiac index was elevated in 4 of 6 patients studied by Epstein et al. (1953); the actual values varied from 4.16 to 5.15 liters/min/m². The index fell considerably during occlusion of the fistula. In 2 subjects, the index was normal and did not

change during occlusion of the fistula. The latter procedure resulted in the expected increase in arterial pressure and slowing of the pulse in all 6 subjects

Muenster et al. (1959) studied 6 patients with fistulas, 2 with overt congestive failure.

Right atrial mean pressure was markedly elevated to 20 mm Hg in the last two. Cardiac index was markedly elevated (4.84 to 8.86) in all patients. Oxygen consumption ranged from 125 to 171 ml/min/m². Arteriovenous differences were depressed and ranged from 1.86 to 2.87 vol per cent. Exercise produced an increase in output in the 4 subjects not in failure. In the 2 subjects in failure, output fell during exercise. Mean pulmonary artery pressure was elevated in all 6 subjects at rest and rose further during exercise.

Bishop et al. (1955) reported similar data in 2 patients with systemic arteriovenous fistulas, viz., an increased cardiac index, decreased arteriovenous difference, and normal oxygen consumption. Pulmonary artery mean pressure was slightly elevated in both. Bishop also reported 11 patients with severe anemia; in 8 subjects the hemoglobin was below 6 Gm/100 ml. Cardiac index was elevated in all, oxygen consumption was normal, and arteriovenous oxygen difference was decreased. Mean pulmonary artery pressure was normal or slightly elevated. Five patients with hyperthyroidism were catheterized by Bishop et al. All had elevated cardiac indexes and oxygen uptakes. Arteriovenous differences were depressed. Pulmonary artery mean pressures were slightly elevated.

Similar data in hyperthyroidism has been reported by Humerfelt et al. (1958), Rowe et al. (1956), and Leight et al. (1956). Humerfelt noted an average cardiac index of 6.1 liters/min/m² in 32 patients. The arteriovenous difference was slightly reduced. Right heart pressures were normal. After therapy, in 16 patients, cardiac index and oxygen consumption fell proportionately so that the arteriovenous differences remained normal. Pulmonary artery pressures decreased slightly after therapy. Rowe's data were similar except for the frequent observation of a normal arteriovenous difference. This investigator also reported that coronary blood flow and ventricular oxygen uptake rose in thyrotoxicosis. Leight has also reported an increased mean coronary blood flow and oxygen consumption in hyperthyroidism.

Blacket et al. (1960) reported hemodynamic observations in 16 patients with heart disease due to thiamine deficiency. Cardiac index varied between 4.2 and 15.5 liters/min/m². Mean oxygen consumption was slightly elevated to 156. Arteriovenous oxygen difference was considerably decreased. Right heart pressures varied considerably. Elevated right atrial mean and right ventricular end-diastolic pressures were observed frequently.

High-output failure has also been reported in Paget's disease. Howarth (1953) investigated 13 cases. In 12 patients with active disease, cardiac output was increased in the 5 in whom study revealed 35 or more per cent skeletal involvement, or more, and plasma alkaline phosphatase levels of more than 45 King-Armstrong units. Arteriovenous oxygen difference was low in these 5 cases, indicating a true high-output state.

HEMODYNAMIC STUDIES IN ATRIAL ARRYTHMIAS

The clinical frequency of atrial fibrillation and atrial flutter has evoked interest in the hemodynamic consequences of these arrythmias. Most studies have demonstrated a rise in resting cardiac output after conversion from atrial fibrillation to sinus rhythm.

Hanssen et al. (1952) studied 14 patients, both at rest and during exercise, during atrial fibrillation and sinus rhythm. Measurements at rest revealed a rise in cardiac output after conversion to sinus rhythm in 9 patients; in 6 of these 9, the cardiac index rose to a normal resting level. In 5 of the 12 patients who were exercised while the rhythm was atrial fibrillation, there was a significant increase in cardiac output over the resting value. The average rise was 18 per cent in the 9 patients who demonstrated an increase in output over the resting value. After conversion to sinus rhythm, 11 of the 12 patients increased their output during exercise as compared to the resting value. In general, therefore, conversion to sinus rhythm resulted in a rise in cardiac output.

Broch and Muller (1957) studied 20 patients before and after conversion to sinus rhythm. Cardiac output and stroke volume increased both at rest and during exercise after restoration of sinus rhythm. Pulmonary artery pressure was unchanged by conversion, but wedge pressure rose after conversion, both at rest and during exercise. Kory and Meneely

of disproportionate elevation of the diastolic and mean pulmonary artery pressures. Right ventricular end-diastolic pressure was markedly elevated, with the typical early-diastolic dip rising to a diastolic plateau (Fig. 18-15). Cardiac index was slightly reduced. These hemodynamic abnormalities, due predominantly to a thickened, poorly distensible pericardium, had completely disappeared 3 months after surgery. A second patient exhibited the same classic hemodynamic findings of constrictive pericarditis but had a normal cardiac index in the absence of clinical signs or symptoms of this disease. A third patient demonstrated that *extensive pericardial calcification* may exist in the absence of hemodynamic or clinical cardiac abnormalities, at least at rest. The fourth subject exhibited a marked reduction in cardiac index, associated with a narrowed pulmonary artery pulse pressure, a high diastolic pressure, and a slightly elevated systolic pressure. Right ventricular end-diastolic pressure was markedly elevated. After acute digitalization during catheterization, cardiac output rose, with a fall in pulmonary artery and right ventricular pressures. This response suggested a failing myocardium in this patient with constrictive pericarditis. The fifth subject showed a normal cardiac output but with right ventricular and pulmonary artery pressure curves characteristic of constrictive pericarditis. After 1 month of intensive therapy, restudy revealed considerable diminution of the hemodynamic signs of constrictive pericarditis. These alterations rendered the concept of the mechanical interference of pericardial constriction per se untenable. The pathogenesis of the hemodynamic abnormalities in this last case remained unclear

Hansen et al. (1951) have published similar data illustrating the typical *early-diastolic dip* in the right atrial and ventricular curves. These dips disappeared after pericardiectomy. Murphy et al (1958) studied 6 patients with constrictive pericarditis Cardiac indexes varied from markedly reduced levels to normal levels Right atrial and right ventricular end-diastolic pressures were typically elevated, as were pulmonary artery pressures Pulmonary artery wedge pressures were also increased On exercise, further increases were noted in right heart pressures In 3 cases, right heart pressures were normal during rest and exercise after surgery.

Wilson et al (1954) have reported similar data in 10 patients with constrictive pericarditis. A right ventricular diastolic dip was present in all patients, together with marked elevation of the right ventricular end-diastolic pressure. A small pulmonary artery pulse pressure was noted. Identical hemodynamic abnormalities were observed in 3 patients with *pericardial effusion*. Wilson stated that the right ventricular diastolic to systolic pressure ratio was greater than 40 per cent in constrictive pericarditis.

It must be emphasized that although the above hemodynamic abnormalities are highly characteristic of constrictive pericarditis, they are not pathognomonic thereof. Balchum et al. (1956) and Clark et al. (1956) have emphasized that patients with *endocardial fibrosis* and *nonspecific myocarditis* may exhibit identical abnormalities.

HIGH-OUTPUT FAILURE

Cardiac failure associated with the high-output state has evoked considerable interest Most cases have been associated with systemic arteriovenous fistulas, anemia, beriberi, and hyperthyroidism. Reduced resistance to outflow of blood from the systemic arterial tree is common to these conditions (Youmans, 1957).

Gorlin et al (1959b) have described a group of 8 subjects with a persistently elevated cardiac output associated with cardiac hypertrophy *and a precordial systolic murmur*. The average *cardiac index* was 6.4 liters/min/m^2. The average oxygen consumption was 177 ml/min/m^2, a figure considerably higher than the basal level of about 125 to 135 ml/min/m^2. The arteriovenous difference was 2.8 vol per cent, a figure comparable to the levels seen in anemia and systemic fistulas with failure. The resting heart rate of 79 suggests that anxiety was not the cause of the elevation in cardiac output. The stroke index was therefore *increased* to 80 ml/beat/m^2. The response *to exercise* was unusual, however, in that cardiac output remained unchanged despite an increase in oxygen consumption. The etiology of these unusual hemodynamic findings is uncertain

Perhaps the most typical example of high-output failure is seen in patients with *systemic arteriovenous fistulas*

Cardiac *index* was *elevated* in 4 of 6 patients studied by Epstein et al. (1953), the actual values varied from 4 16 to 5.15 liters/min/m^2. The index fell considerably during occlusion of the fistula. In 2 subjects, the index was normal and did *not*

16

Treatment of heart failure

SIMON DACK

With better understanding of the myocardial and hemodynamic disturbances associated with heart failure, the treatment of this condition has become increasingly effective.

In previous chapters, it has been shown that the clinical manifestations of failure result primarily from a decrease in cardiac output to a level inadequate for the metabolic needs of the body, and secondarily from renal retention of salt and water, producing increased blood volume and edema in the lungs, viscera, and peripheral regions The latter is a result of the reduced renal blood flow, diminished glomerular filtration, and tubular dysfunction secondary to the reduced cardiac output To be effective, treatment must either improve myocardial function and increase cardiac output, or improve renal function (by affecting either the vascular or the tubular function), thereby producing diuresis of salt and water and eliminating edema Often it is difficult to dissociate the cardiac and renal effects of a procedure or drug.

The therapeutic measures presently available are directed, respectively, at (1) removing or alleviating the intrinsic cardiovascular lesions responsible for cardiac failure, i.e., eliminating the cause, (2) improving the state of the myocardium so that cardiac function and circulatory dynamics are restored to normal or improved, (3) reducing the work of the heart and protecting it from the effects of increased work and strain, and (4) eliminating edema fluid resulting from renal disturbance secondary to the heart failure

BASIC PRINCIPLES OF TREATMENT

The basic principles of treatment for heart failure are (1) to improve myocardial efficiency and increase cardiac output, (2) to reduce venous congestion and edema by dietary salt restriction and diuretic therapy aimed at decreasing reabsorption of sodium and water.

The following therapeutic measures, which comprise the basis of the modern therapy of heart failure, will be discussed: rest; dietary regulation of salt intake, digitalization; diuretic therapy, and ancillary measures to improve cardiac function (oxygen, antibiotics, anticoagulants, steroids, vitamin therapy, etc.).

Importance of Precipitating Factors of Heart Failure. It must be emphasized that in most cases of heart failure, there is an acute precipitating cause for the failure in addition to the underlying cardiac disease. These precipitating causes are (1) infection, generally pulmonary or associated with a bacteremia, (2) tachycardia or cardiac arrhythmia with excessively rapid or slow ventricular rate; (3) strain produced by physical or emotional stress, (4) overloading of the circulation by excessive dietary salt and fluid intake or following parenteral administration of saline solutions; (5) acute myocardial damage by inflammation, toxins, or infarction, (6) progressive impairment of myocardial function by recurrent carditis, ischemia, necrosis, or dilatation, (7) mechanical disturbances, such as those induced by pericarditis and pericardial effusion; (8) improper or inadequate previous therapy, including underdigitalization, overdigitalization, inadequate diuretic therapy, and (9) electrolyte disturbances due to advanced failure and excessive electrolyte loss by diuresis.

A search for these possible precipitating causes is mandatory in every patient, since successful management depends on the recognition and treatment of such correctible intrinsic

(1951) reported similar changes in 6 of 8 patients after restoration of sinus rhythm. Hecht et al. (1951 and 1956) studied 15 patients. While at rest, the mean increase of cardiac output after conversion to sinus rhythm was small but the exercise increase was statistically significant. Pulmonary artery pressure remained unchanged.

Harvey et al. (1955a) catheterized 8 patients with atrial flutter with heart disease of varying causes. Cardiac output was generally low. Pulmonary hypertension of varying magnitude was noted in those in heart failure. Conversion to sinus rhythm in 5 patients resulted in a 40 per cent rise in cardiac output at rest, while oxygen consumption remained unchanged. In 2 patients the response to exercise during flutter was similar to that after conversion to sinus rhythm

Mahrer et al. (1957) reported data in a patient who developed *atrial flutter* during cardiac catheterization and then reverted spontaneously to sinus rhythm during the course of the catheterization. The ventricular rate was the same during both rhythms. Neither cardiac output nor right heart pressure levels were altered by atrial flutter, although exact comparison is made difficult by the fact that the oxygen consumption (ml/min/m^2) was 153 and 131 during atrial flutter and sinus rhythm, respectively.

SUMMARY

The hemodynamic consequences of heart failure in varied types of heart disease have been outlined. *Elevation of the right or left ventricular end-diastolic pressure and of the atrial mean pressure* has been suggested as the initial hemodynamic manifestation of such failure. Changes in cardiac output are generally noted. Congestion of the venous bed behind the failing ventricle eventually follows. The concept of noncardiac circulatory congestion has been discussed by Eichna (1960). The eventual place of this concept in cardiovascular physiology remains to be evaluated.

duce the renal blood flow and increase edema formation. On the other hand, the greater renal blood flow in the horizontal position makes it desirable for the patient to rest in bed for several hours after a mercurial injection in order to increase the diuretic response.

2. In the sitting position, dyspnea and orthopnea are lessened. In fact, the patient with pulmonary congestion may find it impossible to be flat and is comfortable only when propped up in bed or sitting in a chair. The gravity effect of the upright position results in increased drainage of fluid from the lungs and pleural cavities and improved pulmonary ventilation.

3 Body position is a factor in determining the site of edema accumulation. During the day, with the patient in the sitting or upright position, edema tends to occur in the lower and dependent portions of the body At night, however, if the patient resumes the recumbent position in bed, the increased venous return to the right heart may increase the blood flow to the lungs and precipitate acute pulmonary congestion or edema Similarly, overloading of the pulmonary circulation may occur when complete rest in bed is suddenly imposed on patients with long-standing right heart failure and persistent peripheral edema, who have been out of bed or ambulatory.

In the clinical management of patients with heart failure, one must weigh the possible good and bad effects of enforced bed rest. Patients with dyspnea and orthopnea due to acute left heart failure are put to bed and propped up with pillows and back rests as high as is consistent with comfort, but as soon as feasible they should be allowed to sit up in a chair for increasing periods In cases where the patient is kept in bed for long periods, the measures outlined in Part 19, Chap. 3 should be carried out to prevent peripheral venous stasis and thromboembolism (encouraging movement of lower limbs, elastic bandaging of the legs, anticoagulant therapy, care of bowel function, use of bedside commode, etc)

DIETARY REGULATION OF SALT INTAKE

Despite the availability of potent diuretics to increase the excretion of excess sodium, regulation of dietary sodium intake remains an important part of the management of failure. (A more complete discussion of this subject is given in Part 19, Chap. 5.) An adequate clinical response to diuretic and digitalis therapy depends upon restriction of salt intake to a level which the kidneys can handle. It has been claimed that there is a direct linear proportion between dietary salt intake, urinary sodium excretion, and response to diuretic agents.

The degree of dietary salt restriction required must be individualized in each case and is dependent on the severity and progression of the congestive symptoms and edema. Severe sodium restriction to 500 to 800 mg daily is generally necessary in acute failure or in chronic failure with massive edema. This will generally increase the saluretic response to diuretic therapy and permit reduction in dosage and frequency of administration, minimizing the danger of toxic effects. In patients with a moderate degree of failure, particularly after the edema has disappeared, the salt intake can be more liberal Such patients may be kept edema-free with only mild to moderate salt restriction (abstention from salty foods, and eliminating salt in the cooking and the salt shaker at the table), supplemented with a daily oral thiazide derivative, and occasional mercurial injection if necessary. In patients with only mild heart failure, or those who have completely recovered from acute failure, only slight limitation of salt intake is necessary. The trend in recent years has been to be more liberal with salt intake in such patients, provided maintenance therapy with digitalis and the potent oral diuretics is continued. This may obviate the necessity for prolonged salt restriction Close observation for detection of recurrent edema is indicated to determine the necessity of resuming restriction of salt intake.

DIGITALIS THERAPY

Digitalis is the most important drug in the treatment of heart failure.

Its clinical use is based on the following physiologic actions:[1]

1 The vagal stimulating effect depresses conduction through the AV conduction system. This results in slowing of the ventricular response when atrial arrhythmias (flutter and fibrillation) are associated with congestive failure. Similarly, the vagal stimulation may depress the SA node and slow the heart rate in the presence of normal sinus rhythm, but this effect is not significant

[1] See Part 21, Chap 10. *Editor.*

and extracardiac factors. In addition, other predisposing causes of heart failure that may require treatment should be looked for, such as hyperthyroidism, hypothyroidism, vitamin B deficiency, pulmonary embolism, extra- or intracardiac shunts, and other cardiovascular lesions amenable to surgery such as valvular or infundibular stenosis, constrictive pericarditis, etc. It is evident that no form of treatment will be completely successful unless these predisposing causes are recognized and alleviated.

Factors Determining Response to Therapy. The cardiac reserve is determined by the type and duration of the heart disease, the severity of the complications and precipitating factors, and the response to therapy. Depending on these factors, cardiac reserve may be restored to its original state following recovery from heart failure or the patient may be left with a diminished reserve. With repeated bouts of failure, the cardiac reserve may progressively diminish and the patient may lapse into a state of chronic persistent failure.

The response to therapy, therefore, determines the degree of cardiac reserve of the patient, for when he is first seen, the manifestations of failure may be the same regardless of the stage of his heart disease. The response to therapy is obviously better in the early stages of heart disease than in the terminal stages Therefore, a good response to therapy (good cardiac reserve) determines the prognosis for each patient. The basic aim in treatment should be to restore myocardial efficiency and cardiac reserve to a maximal degree so that the patient can resume an ambulatory status and carry on his everyday activities This is generally attainable in patients with initial bouts of failure or when there are precipitating factors that can be recognized and controlled

REST

Physical activity may produce several deleterious effects on the patient with cardiac failure. (1) oxygen consumption, heart rate, cardiac output, and cardiac work are increased; (2) myocardial oxygen consumption is increased and myocardial hypoxia may occur in the hypertrophied, dilated, or ischemic heart, (3) renal blood flow and glomerular filtration are reduced during exercise, resulting in increased salt and water retention. For these reasons, cardiac failure may be precipitated or aggravated during physical effort or emotional stress. On the other hand, in the resting state, the oxygen consumption and circulatory and metabolic needs of the body are reduced, so that the failing heart, even with its reduced output, can better meet the circulatory requirements of the body. Furthermore, the renal blood flow is improved in the resting state in the supine position, resulting in increased glomerular filtration and diuresis of salt and water.

These considerations make it desirable to impose some degree of physical and emotional rest on all patients with heart failure so as to minimize the demands on the cardiovascular system. The degree of restriction of activity must be individualized in each case, depending on the severity of the underlying cardiovascular damage and heart failure. It may vary from a modification of the daily mode of life in mild cases (shorter work hours, frequent rest periods, avoidance of fatiguing travel) to complete bed rest and avoidance of all physical activity in severe cases. In cases of mild failure with impaired exercise tolerance, a short period of confinement to the home or hospital room may be desirable, with activities limited to chair rest and bathroom privileges. In more severe cases, a longer period of complete rest in bed or chair is necessary, and walking is avoided until the signs of failure disappear. This period may range from several days to several weeks or months. In such cases, the possible dangers of prolonged immobilization in bed should be considered.

Posture: Bed vs. Chair Rest. In Chap 3 of Part 19 it will be pointed out that prolonged immobilization in bed in the horizontal position may produce deleterious cardiopulmonary effects, and that dyspnea and orthopnea may improve sooner when the patient with cardiac failure is allowed to sit up in a chair. It was emphasized that body position plays an important role in the circulatory effects of rest. In the normal person, cardiac output is increased in the horizontal position, because of increased venous return to the heart, and is reduced in the sitting posture, because of decreased venous return. Although this physiologic adjustment is less marked in the cardiac patient, it may be associated with beneficial as well as deleterious effects during heart failure

1. Since the physiologic and metabolic demands on the heart are less in the sitting position than during recumbency, the work of the heart is diminished. However, the reduced cardiac output in the sitting position may re-

TABLE 18-21. CHARACTERISTICS OF THE DIGITALIS GLYCOSIDES

Digitalis glycosides	Commercial preparation and manufacturer	Onset of action	Peak effect, hr	Marked regression	Complete disappearance of effect, days
Administered intravenously:					
Strophanthin G	Ouabain (Arnaud)	5 min	½-2	10 hr	1-1½
Deslanoside	Cedilanid D (Sandoz)	15 min	1-2	24 hr	2-5
Digoxin	Lanoxin (B and W.)	15 min	1½-5	10 hr	3-5
Digitoxin	Digitaline Nativelle	15-30 min	6-8	2 days	10-14
Acetyl-digitoxin	Acylanid (Sandoz)	15-30 min	5-6	2 days	7-10
Administered orally:					
Digoxin	Lanoxin (B and W.)	1-3 hr	6	18 hr	5-7
Gitalin	Gitaligin (White)	2-4 hr	8-10	1-2 days	7-10
Acetyl-digitoxin	Acylanid (Sandoz)	2-4 hr	8-10	2 days	7-14
Digitoxin	Digitaline Nativelle Crystodigin (Lilly) Purodigin (Wyeth)	2-4 hr	12	2 days	10-14
Digitalis leaf	Digitalis U S P	3-6 hr	36	2 days	10-21

G) and *strophanthin K*. The available commercial preparations, their route of administration, onset, and duration of action are shown in Table 18-21.

Specific Characteristics of Various Digitalis Preparations

1. *Ouabain and strophanthin* are the most potent agents available. As seen in Table 18-21, following intravenous injection, they have extreme speed of action and onset of peak effect, and rapid rate of dissipation. This makes them ideally suited for emergency therapy. They are not absorbed when taken orally.

2. *Deslanoside* (*acetyl-lanatoside C or Cedilanid D*) is derived from lanatoside C. It is similar to digoxin in its action but may have a more rapid action and an earlier peak effect. *It is therefore suitable for emergency therapy and for rapid digitalization by either intravenous or intramuscular injection.* Its rapid dissipation makes it unsuitable for oral maintenance therapy.

3. *Digoxin* is suitable for both parenteral and oral digitalization and for long-term maintenance. It may be more difficult to establish a stable maintenance dose with digoxin than with other preparations because of its relatively rapid dissipation. However, *this makes it a desirable drug in situations where rapid withdrawal of digitalis is desirable or where digitalis toxicity is likely to occur* (*as in potassium depletion, elderly individuals, etc.*)

4. *Digitoxin*, one of the most widely used glycosides, is an excellent preparation for both intramuscular and oral use initially, and *is particularly suited for long-term oral maintenance* because of its constancy of absorption and relatively slow dissipation. It is also said to cause less gastrointestinal irritation. Because of this, however, one must guard against overdosage and cumulative effects.

5. *Digitalis leaf* has been largely replaced by the more purified glycosides during initial, oral digitalization, particularly when a rapid effect is desired. Its use is associated with a higher incidence of nausea and vomiting. However, it remains a satisfactory preparation for oral maintenance therapy because of its slow dissipation; here, too, one must guard against cumulative effects.

6. *Gitalin* lies between digoxin and digitoxin in its speed of action and peak effects and rate of dissipation. It has been claimed that its therapeutic range is greater than that of other glycosides, and that digitalization can be attained with a lower incidence of toxicity. It is a good drug for oral digitalization and for maintenance therapy, particularly in patients who have previously shown toxic effects from other preparations.

OTHER DIFFERENCES IN CLINICAL EFFECTS. Recent clinical studies (Aravanis *et al.*) have shown qualitative and quantitative differences among the various glycosides when administered parenterally, which can be applied to clinical situations:

2. The direct myocardial action increases the force of myocardial contractions by a mechanism not sufficiently understood.

3. Digitalis enhances the mechanical efficiency of the contractile units of the failing myocardium by restoring a more smooth transition from chemical energy (ATP, ADP) to mechanical energy of contraction. This makes the drug highly effective in clinical states associated with hypertrophy and dilatation of the cardiac fibers without too much damage but with low cardiac output. In such states, the diminished contractile response of the failing myocardium to an undiminished supply of chemical energy can be improved, and the cardiac output increased. The effect is inadequate in toxic and inflammatory disorders affecting the energy-supplying areas of the cardiac fiber (nucleus and mitochondria), as in diphtheritic or viral myocarditis.

4. Digitalis decreases the diastolic length of the failing cardiac fibers, diminishes their oxygen consumption for any given work output, and thereby increases the work capacity and efficiency of the failing heart.

5. Since digitalis does not affect the energy-producing mechanism of the cardiac fiber, it is of little value in heart failure associated with high cardiac output due to causes which affect the metabolic processes of the myocardium, such as thyrotoxicosis or beriberi

Digitalization, therefore, in conjunction with rest, constitutes the most effective direct measure for increasing the efficiency and output of the heart, in contradistinction to diuretics, which alleviate edema primarily by their effects on the kidney.

Clinical Indications. Digitalis is indicated in almost all types of heart failure, whether purely left-sided, right-sided, or combined, whether acute or chronic, and of all causes. It should be the initial treatment and should not be replaced by diuretics except in special circumstances It is effective in heart failure caused by congenital, rheumatic, hypertensive, or arteriosclerotic heart disease with cardiac dilatation, impaired myocardial contraction, and reduced cardiac output It is of particular value in heart failure associated with paroxysmal tachycardia or other arrhythmias with rapid ventricular rate resulting in inefficient atrial and ventricular contractions. It is of less value in acute inflammatory and toxic myocardial involvement, as in acute myocarditis (bacterial, viral, rheumatic) or acute necrosis of the myocardium (myocardial infarction), where the damage is extensive and results in lysis of the energy-forming parts of the myocardial cells. Even in these conditions, the drug may be of value if the myocardial involvement is not too widespread and if there are remaining viable but dilated cardiac fibers whose mechanical efficiency can be sufficiently improved to restore some degree of cardiac compensation As already stated, the drug is not too effective in metabolic and nutritional disorders resulting in failure (hyper- and hypothyroidism, beriberi and anoxic states, and pulmonary disorders resulting in cor pulmonale). Although *digitalis is not contraindicated in these conditions*, it must be kept in mind that, despite adequate digitalization, heart failure will not be controlled unless the underlying cause is adequately treated.

Pharmacologic Differences of Various Glycosides and Their Clinical Applications. Most digitalis preparations have basically the same action on the heart, but there are qualitative and quantitative differences which are related to differences in rate and degree of absorption and excretion, potency, onset of peak effect, and duration of action.[2] These differences determine the suitability of the various glycosides for oral and parenteral use, for rapid digitalization, and long-term maintenance therapy. The practicing physician would find it difficult to use every available preparation, but he should become familiar with the several oral and parenteral preparations for routine use and should be aware of the effects of all the other preparations and their availability for special situations

There are three main glycosides: digitoxin, gitoxin, and digoxin, which are derived from two digitalis plants, *Digitalis lanata* and *Digitalis purpurea* (Fig. 21-31) Of these, only *digitoxin* and *digoxin* and their derivatives have important cardiac effects Intermediate preparations of the digitoxin glycosides are *lanatoside A* and *acetyl-digitoxin;* of the digoxin glycoside, *lanatoside C, acetyl-digoxin*, and *desacetyl-lanatoside C* (*deslanoside, Cedilanid D*)

Gitalin is derived from *D. purpurea* and is a combination of glycosides (gitoxin, digitoxin, gitaloxin, strospeside). Digitalis (USP) is a dried extract of the whole leaf of *D. purpurea* containing variable amounts of the above glycosides.

The strophanthus plants yield two complexes of rapidly acting glycosides· ouabain (*strophanthin*

patients and in those with mild to moderate degrees of failure

INITIAL DIGITALIZATION. *There is no fixed dosage for optimal digitalization and no mathematic method for determining dosage.* The dose necessary to achieve the desired therapeutic effect without producing toxicity must be reached carefully in each patient. The size of the initial dose and of subsequent doses, as well as the interval between doses, depends on the severity of the heart failure and the acuteness of the symptoms. Thus, digitalization can be achieved either rapidly or slowly, depending on the size and frequency of the dosage and the amount by which the total 24-hr dose exceeds the amount excreted or dissipated in the body. There may be wide variations in the required dosage from patient to patient

Rapid digitalization is achieved by giving a relatively large initial dose of the drug, either orally or parenterally, followed by a smaller dose at 6- to 12-hr intervals for 24 to 48 hr. The initial dose is generally one fourth to one-half of the average total digitalizing dose of each preparation (Table 18-22), and the subsequent doses generally range from one-sixth to one-fourth of the total dose With this method, a full therapeutic effect can be obtained within 48 hr The onset of clinical improvement is generally evident after about half the digitalizing dose has been given.

When digitalization has been started with a parenteral preparation (deslanoside, 0.8 mg intravenously), it can be continued by giving an oral preparation the same day.

According to Neumann and Reich, 0.4 mg digitoxin should be given orally on the same day as the intravenous injection, a similar dose should be given on the following day; then, 0.2 mg should be given on the third day, followed by a maintenance daily dose of 0.1 mg if a full therapeutic effect has been obtained. A slightly less effective scheme consists of 0.2 mg on the day of the injection, as well as on the second and third days.

Moderately rapid digitalization may be achieved by giving one-third of the minimal recommended therapeutic dose daily in two divided doses for 3 days For example, digitoxin 0.2 mg is given twice daily for 72 hr, for a total of 1.2 mg A therapeutic effect (decrease of dyspnea and edema, slowing of heart rate, etc.) should become evident by this time in most patients. One-half this dosage can be continued cautiously for several days if a full therapeutic effect has not been obtained, and then the usual daily maintenance dose of 0.1 mg is started

Slow digitalization, usually indicated in ambulatory patients with mild failure, is attained by giving a small fraction of the average total therapeutic dose (one-eighth to one-sixth), three times daily for 3 to 4 days, and by then reducing to twice daily until a good clinical

TABLE 18-22. AVERAGE THERAPEUTIC DOSE OF DIGITALIS PREPARATIONS (24 TO 48 HR)

Preparation	Parenteral			Oral			
	Initial	*Subsequent*	*Total*	*Initial*	*Subsequent (4–6 hr)*	*Total*	*Daily maintenance dose*
Ouabain, mg	0.5	0.25–0.5	0.5–1.0	Not used

Digitalis leaf, Gm		Not used		0.4–0.8	0.2–0.4	1.6 (1–3.5)	0.1

1. Digoxin and deslanoside produced the greatest slowing of the heart rate, making them preferable in severe tachycardias and atrial arrhythmias.

2. Ouabain (first and second days) and digitoxin (second day) caused the fastest onset of improvement, as compared with digoxin and gitalin (third day) and acetyl-digitoxin (third to fourth days). This rapid effect of parenterally administered digitoxin has not been sufficiently appreciated.

3 Digitoxin, acetyl-digitoxin, and digoxin produced the best effect on cardiac dilatation (shown by radiography) and venous engorgement (shown by size of liver, venous pressure, and circulation times).

4. The greatest effects on the electrocardiogram (RS-T depression and T-wave inversion) were caused by digitoxin. Acetyl-digitoxin, deslanoside, and digoxin produced the greatest clinical improvement with least electrocardiographic change. This would suggest that when severe electrocardiographic changes are present because of myocardial damage and left ventricular strain, these preparations are preferable to digitoxin

5. The minimum toxic reactions were observed with deslanoside, followed by acetyl-digitoxin and digitoxin, making these, especially deslanoside, the preferred preparations in patients with low threshold of toxicity A relatively high incidence of toxicity occurred with digoxin, probably because the generally recommended dosage for parenteral administration has been too high (3 mg in 48 hr instead of 2 mg).

These pharmacologic differences in the various digitalis preparations would suggest the following clinical applications in the management of patients with heart failure:

1 In mild to moderate failure, especially in ambulatory patients, one should digitalize orally by slow or rapid method with digitalis leaf, digitoxin, acetyl-digitoxin, gitalin, or digoxin.

2. In severe failure and in situations of moderate urgency, one should digitalize rapidly and orally with digoxin, gitalin, digitoxin, or acetyl-digitoxin.

3. For emergency situations, such as acute pulmonary edema and severe tachycardia, one should digitalize rapidly and parenterally with ouabain, deslanoside, digoxin, or digitoxin.

Dosage and Methods of Administration. There are several cardinal principles of successful digitalis therapy.

1. The physician should be familiar with the characteristics of each available preparation, as already discussed and outlined in Tables 18-21 and 18-22.

2. The specific preparation should be given in adequate dosage to produce the optimum therapeutic effect.

3. Dosage should be carefully regulated to avoid risk of toxicity.

4. The type of preparation used and the route of administration depend on the urgency of the clinical situation and the severity of the heart failure.

Initial digitalization in a previously undigitalized or underdigitalized patient should be considered a clinical experiment; it is basically an attempt by trial and error to administer a therapeutically effective dose without producing toxic symptoms. Although the therapeutic dose for individual patients varies, there is generally an optimum therapeutic range for each digitalis preparation, below which the clinical response is inadequate, and above which toxicity will generally develop. After the desired therapeutic effect is obtained, the dosage is reduced to a maintenance dose calculated for each patient

ROUTE OF ADMINISTRATION. The parenteral administration of a digitalis preparation, either intravenously or intramuscularly, is indicated only in acute emergencies, such as pulmonary edema and acute heart failure associated with serious cardiac arrhythmias or excessive tachycardia It also may be indicated in patients with nausea and vomiting who cannot take oral medication. Ouabain, strophanthin, deslanoside, digoxin, and digitoxin can be given parenterally The first two must be given intravenously, the last three may be given intravenously or intramuscularly. In patients in shock or with severe tissue edema, absorption following intramuscular injection may be irregular and local tissue irritation and occasional necrosis may occur. The oral route is suitable for the great majority of patients with failure. Peak effects can be obtained within several hours, and excellent therapeutic results may be achieved within 1 to 3 days with any of the available oral preparations mentioned previously. It is the preferable route for ambulatory

patients and in those with mild to moderate degrees of failure.

INITIAL DIGITALIZATION *There is no fixed dosage for optimal digitalization and no mathematic method for determining dosage.* The dose necessary to achieve the desired therapeutic effect without producing toxicity must be reached carefully in each patient. The size of the initial dose and of subsequent doses, as well as the interval between doses, depends on the severity of the heart failure and the acuteness of the symptoms. Thus, digitalization can be achieved either rapidly or slowly, depending on the size and frequency of the dosage and the amount by which the total 24-hr dose exceeds the amount excreted or dissipated in the body. There may be wide variations in the required dosage from patient to patient.

Rapid digitalization is achieved by giving a relatively large initial dose of the drug, either orally or parenterally, followed by a smaller dose at 6- to 12-hr intervals for 24 to 48 hr. The initial dose is generally one-fourth to one-half of the average total digitalizing dose of each preparation (Table 18-22), and the subsequent doses generally range from one-sixth to one-fourth of the total dose. With this method, a full therapeutic effect can be obtained within 48 hr. The onset of clinical improvement is generally evident after about half the digitalizing dose has been given.

When digitalization has been started with a parenteral preparation (deslanoside, 0.8 mg intravenously), it can be continued by giving an oral preparation the same day.

According to Neumann and Reich, 0.4 mg digitoxin should be given orally on the same day as the intravenous injection; a similar dose should be given on the following day; then, 0.2 mg should be given on the third day, followed by a maintenance daily dose of 0.1 mg if a full therapeutic effect has been obtained. 3. For emergency situations, such as acute pulmonary edema and severe tachycardia, one should digitalize rapidly and parenterally with *ouabain, deslanoside,* digoxin, or digitoxin.

Dosage and Methods of Administration. There are several cardinal principles of successful digitalis therapy.

1. The physician should be familiar with the characteristics of each available preparation, as already discussed and outlined in Tables 18-21 and 18-22.

2. The specific preparation should be given in adequate dosage to produce the optimum therapeutic effect.

3. Dosage should be carefully regulated to avoid risk of toxicity.

4. The type of preparation used and the route of administration depend on the urgency of the clinical situation and the severity of the heart failure.

Initial digitalization in a previously undigitalized or underdigitalized patient should be considered a clinical experiment; it is basically an attempt by trial and error to administer a therapeutically effective dose without producing toxic symptoms. Although the therapeutic dose for individual patients varies, there is generally an optimum therapeutic range for each digitalis preparation, below which the clinical response is inadequate, and above which toxicity will generally develop. After the desired therapeutic effect is obtained, the dosage is reduced to a maintenance dose calculated for each patient.

ROUTE OF ADMINISTRATION. The parenteral administration of a digitalis preparation, either intravenously or intramuscularly, is indicated only in acute emergencies, such as pulmonary edema and acute heart failure associated with serious cardiac arrhythmias or excessive tachycardia It also may be indicated in patients with nausea and vomiting who cannot take oral medication. Ouabain, strophanthin, deslanoside, digoxin, and digitoxin can be given parenterally. The first two must be given intravenously, the last three may be given intravenously or intramuscularly. In patients in shock or with severe tissue edema, absorption following intramuscular injection may be irregular and local tissue irritation and occasional necrosis may occur. The oral route is suitable for the great majority of patients with failure. Peak effects can be obtained within several hours, and excellent therapeutic results may be achieved within 1 to 3 days with any of the available oral preparations mentioned previously. It is the preferable route for ambulatory

advanced cardiac disease with failure, the myocardium may become unresponsive to the usually recommended maintenance dose and toxicity may occur before a therapeutic effect. In such patients, the maintenance dose will be the largest dose the patient can tolerate without causing toxic effects.

Average Predicted Dose for Each Preparation. Comparative studies on ambulatory patients have indicated the following comparable *maintenance doses* (Table 18-23) to be adequate in about 75 per cent of patients. Generally, with slowly excreted glycosides (digitoxin), the maintenance dose is about one-tenth the digitalizing dose. With more rapidly excreted glycosides (digoxin) this fraction increases to about one-sixth to one-eighth. If an inadequate response is observed with this dose, then it should be increased by 50 per cent or doubled until the desired effect is obtained Also, it may be helpful to switch from one preparation to another, and determine by trial and error whether one is preferable to the other. It can be seen in Table 18-23 that *the usual maintenance dose of the leaf* (0 1 Gm) *is equivalent to 0 1 mg digitoxin, 0 5 mg digoxin, 0 5 mg gitalin, and 1 0 mg deslanoside.* Although these dosages will be therapeutically effective in about 75 per cent of patients, a smaller group (15 per cent) may require a larger dose, and a small percentage (10 per cent) may show toxic signs with the recommended dosage In about 10 per cent of patients, no therapeutic effect can be maintained with any of the digitalis preparations

GUIDES TO DETERMINING MAINTENANCE DOSAGE

Control of Congestive Signs As in initial digitalization, the best guide to determining adequate maintenance dosage is the effect on edema and other signs of failure. If signs of early failure recur (ankle edema, increased weight), the maintenance dose should be doubled for several days. Such intermittent increase in dosage may be necessary frequently. With few exceptions, patients with class II or III heart disease who have been digitalized during bouts of acute heart failure should continue the digitalis maintenance therapy indefinitely. Stopping the drug for more than a few days may result in recurrence of edema, dyspnea, or other signs of failure unless the patients are receiving other potent diuretics. However, if the patient is completely free of signs of failure, skipping the dose for 1 or 2 days each week, particularly if digitoxin or whole leaf is used, may be adequate for maintenance and help to prevent toxicity. Also, the daily maintenance dose can be reduced, for example, digoxin 0.25 mg rather than 0 5 mg.

Heart Rate When atrial fibrillation is present, the ventricular response should not be allowed to slow below 50 beats per minute and preferably should not be more than 80 beats per minute at rest When normal sinus rhythm is present, the heart rate is not a good guide to maintenance dosage, except that either marked tachycardia or bradycardia may be a sign of digitalis toxicity. Ordinarily, however, there is no indication for discontinuing or skipping the daily dose when the rate falls to 60 beats per minute or even less.

Electrocardiogram. The severity of the electrocardiographic changes produced by digitalis is no effective guide to the degree of digitalization necessary for maintaining dosage: RS-T and T-wave changes may occur even when the dosage is inadequate, and toxicity may be

TABLE 18-23 MAINTENANCE DOSAGE OF DIGITALIS PREPARATIONS

Drug	*Average daily maintenance dose*	*Range*	*Ease of maintenance*	*Dissipation*	*Duration of toxic effects*
Deslanoside, mg	1 0	0 75–1 25			
Digoxin, mg	0 5	0 25–0 75			
Gitalin, mg	0 5	0 5–0 75			days)
Digitoxin, mg	0 1	0.075–0 125			[illegible] days)
Acetyl-digitoxin, mg	0 1	0 1–0 2	Good	Moderate (2 wk)	Short (1–3 days)
Digitalis leaf, Gm	0 1	0 05–0 15	Good	Slow (2 wk)	Prolonged (3–10 days)

effect is observed, generally within 1 week, or until toxic signs appear. A similar result can be attained by giving a single daily dose, generally equal to one and one-half to two times the average maintenance dose, for 1 week, and then starting the daily maintenance dose.

Guides to Optimal Therapeutic Dosage. The average range of the therapeutic and toxic doses for several commonly used digitalis preparations is given in Table 18-22, for both initial digitalization and maintenance. These average dosages have been determined empirically by clinical observation in large groups of patients (Batterman, Luisada). A good and prompt clinical effect can be attained in most cases by adhering to these recommended dosage schedules. However, the optimal dose for each individual must be determined by the effects on the clinical manifestations of the heart failure. Except in severe heart failure, it is not necessary or practical to try to attain maximal dosage. In such cases, the dosage may be cautiously increased above the recommended therapeutic dose until the desired improvement is observed or until signs of digitalis toxicity begin to appear. Then the dose is reduced to the recommended average maintenance dose.

The following criteria may serve as useful guides in determining when the digitalizing dose is adequate:

SLOWING OF HEART RATE. In the presence of atrial fibrillation, the ventricular rate is a sensitive index of the level of digitalization. Slowing of the apical rate to 60 to 70 per minute at rest and disappearance of a pulse deficit are the desired effects. After exercise or excitement, the apical rate should not increase more than 10 to 20 beats per minute. In the presence of normal sinus rhythm, however, the effect on heart rate is much less striking, but here, too, slowing of the rate is an excellent indication of improved myocardial function. Since clinical improvement may appear before there is significant slowing of the heart rate, the latter should not be used as the only guide to dosage. Unlike the case of atrial fibrillation, where the slowing of the ventricular rate may be due largely to vagal stimulation and depression of AV conduction, the slowing of sinus tachycardia is chiefly due to the myocardial effects of digitalization (increased stroke output). In the presence of fever, infection, or hyperthyroidism, one should not expect to reduce the heart rate to normal levels. Attempts to do so would result in digitalis toxicity.

DIURETIC EFFECT. This is the most important indication of a good therapeutic effect. A good diuresis with progressive weight loss and disappearance of edema and other congestive signs indicates restoration of myocardial efficiency, increased cardiac output, and reversal of the hemodynamic disturbances in the kidney.

DISAPPEARANCE OF VENOUS CONGESTION. Disappearance of dyspnea and orthopnea, edema, and enlarged liver are excellent guides to a good clinical effect. These signs result from the improved myocardial function, diuresis, and direct effect on venous circulation. Observation of the venous pressure and circulation time provides a simple objective confirmation of this result.

CARDIAC SIZE. Decrease of diastolic heart size, shown by serial roentgenograms, indicates decreasing cardiac dilatation and is one of the important therapeutic effects of full digitalization.

Maintenance Therapy. The maintenance dose of any digitalis preparation is that amount required to maintain the improved myocardial efficiency produced by initial digitalization. *It varies with the rate of dissipation, cumulative action, and therapeutic range of each preparation, and with the cardiac reserve of the patient.* Regulation of the maintenance dose is of great importance. An inadequate dosage may allow the therapeutic effect to be dissipated, and the failure to recur; too large a dose may cause digitalis toxicity. Similarly, skipping the dose, even for a few days, may bring the patient's digitalis concentration below the therapeutic level, and signs of failure may recur.

DETERMINATION OF MAINTENANCE DOSE. Like calculation of the therapeutic dose for initial digitalization, determination of the daily maintenance dose is also a matter of trial and error. With each digitalis preparation, it depends on several factors.

The Amount of Drug Necessary to Achieve Full Digitalization. It is evident that a patient who required 4.0 mg digoxin initially will require a larger maintenance dose (probably 0.5 mg) than one who required at first only 2.5 mg (probably 0.25 mg).

The Severity of the Underlying Cardiac Disease. Patients with hypertrophied hearts generally require a larger maintenance dose. However, with increasing cardiac damage and in

by vomiting, salivation, and occasionally diarrhea. These symptoms may occur with either oral or parenteral medication and are central in origin. They occur several hours after administration of a large dose or during prolonged maintenance therapy, and are generally persistent. They must be distinguished from the occasional local gastrointestinal irritation, which is generally a temporary side effect, and from the nausea and vomiting of right heart failure produced by engorgement of the gastrointestinal tract and liver, which improves with therapy. Gastrointestinal irritation is more frequent with whole digitalis leaf, because of the presence of gitoxin, and less frequent with the pure glycosides.

Neurologic Symptoms and Signs. These are caused by visual and cerebral irritation and depression, and are manifested by headache, mental depression, confusion or delirium (especially in elderly patients), vertigo, yellow vision and other disturbances in color vision, and retrobulbar neuritis producing scotomas and transient blindness.

Cardiac Manifestations. These are produced by (1) increased irritability of the atrial and ventricular myocardium and of the SA and AV nodal pacemakers, causing various types of arrhythmia and tachycardia, (2) depression of the SA and AV nodal pacemakers and of the AV conduction system, causing a variety of conduction disturbances, and (3) disturbance of cardiac contractility due to degeneration and necrosis of the myocardium.

1. *Myocardial irritability* may produce numerous *ectopic rhythms*, particularly atrial or ventricular premature beats, atrial or ventricular tachycardia, and AV *dissociation* (double tachycardia). *Ventricular extrasystoles* and *bigeminal rhythm* are often the earliest signs of toxicity and may progress to multifocal ectopic beats and unidirectional or bidirectional ventricular tachycardia. *Atrial tachycardia with block* is a characteristic manifestation of digitalis toxicity but is not specific for it, occurring occasionally in undigitalized patients. Other atrial arrhythmias, such as *atrial flutter* and *atrial fibrillation*, may occur but are less common. Intensification of sinus tachycardia may also be a toxic sign.

2. *Disturbances of conduction*, including sinus bradycardias, SA *block*, nodal bradycardia, and wandering pacemaker, may occur because of the direct depressant effect of the drug on the SA and AV pacemakers and because of vagal stimulation. Impaired AV conduction may result in all degrees of *AV block*, from prolongation of the P-R interval to partial block with dropped beats and Wenckebach periods, to complete AV block. Regularization of ventricular rhythm in long-standing atrial fibrillation may be due to AV block rather than reversion to normal rhythm.

3. *Myocardial degeneration and necrosis* produced by digitalis overdosage may result in increasing severity of heart failure, often following an initial improvement. In such cases the failure may decrease when the digitalis is discontinued.

DIAGNOSIS OF DIGITALIS TOXICITY AND ITS PREVENTION

1. *The sudden appearance of any cardiac arrhythmia* in a patient receiving digitalis should be suspected to be a sign of digitalis toxicity. This may occur with large oral doses or intravenous therapy, especially when the patient has previously received digitalis. Serious cardiac arrhythmias may occur in the absence of gastrointestinal or neurologic symptoms.

2. *Loss of appetite and anorexia* are the most common symptoms of toxicity during maintenance therapy. The patient must be alerted to their significance so that the drug can be stopped promptly.

3. *Periodic check of serum electrolytes* is important when the patient is receiving combined digitalis and diuretic therapy. *Acidosis* and *hypopotassemia* may predispose to myocardial irritability and ectopic rhythms. To prevent hypopotassemia, the diuretic agent should be supplemented with potassium salts, such as potassium chloride, 0.5 Gm t.i.d., or potassium Triplex (a combination of potassium chloride, nitrate, and citrate), 5 ml t.i.d.

4. *Calcium salts* should be given with caution to digitalized patients because of their synergistic action. Also, large amounts of oral or parenteral carbohydrates should be avoided, as well as hyperinsulinism.

5. *Acetyl-strophanthidin Test for Digitalis Toxicity:* When digitalis toxicity is suspected, it is generally safe to discontinue the drug temporarily to observe whether the symptoms or cardiac signs disappear. In severe failure, however, it may be difficult to determine if the patient is under- or overdigitalized. Stopping the drug may lead to increasing failure if the patient is underdigitalized, and continuing the

reached without significant electrocardiographic changes. A slightly prolonged P-R interval also has no significance. However, cardiac arrhythmias and a more advanced degree of AV block indicate digitalis toxicity and are indications for temporarily discontinuing and then lowering the maintenance dose.

DURATION OF MAINTENANCE THERAPY. As stated above, when a dilated, damaged heart has failed, and compensation has been restored with digitalis and other diuretic therapy, it is generally advisable to continue maintenance digitalization indefinitely, in an attempt to prevent recurrent bouts of failure. This applies to heart failure produced by arteriosclerotic, hypertensive, and valvular heart disease. However, not infrequently heart failure may occur in a patient with mild heart disease under the influence of severe overloading of the circulation. In such a patient, the cardiac reserve is restored to normal when the precipitating factor is eliminated and heart failure would not be expected to recur except under unusual circumstances.

Examples of this situation are surgical and postoperative stresses, pregnancy, severe pneumonia, etc. In such cases, digitalis maintenance may be cautiously discontinued several months later if cardiac function appears normal. Similarly, a patient with heart failure due to acute myocardial infarction or acute myocarditis may recover completely and subsequently may show no cardiac enlargement and normal cardiac reserve. Such a patient may remain free of failure when digitalis is discontinued, provided other measures are followed to avoid overloading of the heart and circulation, such as avoidance of excessive exertion, low salt intake, intermittent diuretic therapy, etc. Before and after discontinuing or lowering the dose of digitalis, the patient's response to increased activities should be carefully observed, since his digitalis requirement is greater when he is active than when he is at rest, and the signs of recurrent failure may be delayed for several weeks after the digitalis effect is completely dissipated.

Digitalis Toxicity. With the wide use of highly purified and potent glycosides and the introduction of more potent oral diuretics, the problem of digitalis toxicity remains serious. It is related to several factors.

1. The range between the effective therapeutic level and the toxic level of all digitalis preparations is relatively small. In many cases, the toxic dose may be reached before a good clinical response is obtained, particularly in advanced heart disease. For this reason, it is again emphasized that active digitalization should not be carried out by a fixed dosage schedule, and that the clinical status and the electrocardiogram should be checked carefully before each dose change.

2. There is a wide variation in the dose of any digitalis preparation required to produce a good therapeutic response or a toxic effect. Although the average predicted digitalizing dose may be effective and safe in approximately two-thirds of patients, a small group may require up to double this amount to achieve a clinical effect and other patients may develop toxic signs before the therapeutic dose has been reached.

3. Elderly patients, generally those over 60 years of age, may require less digitalis for a therapeutic effect because of slower dissipation and excretion. Also, a sensitive carotid sinus may be activated by the vagal effects of digitalis, producing undesirable effects on the heart rate and rhythm.

4. Patients with severe right heart failure may excrete digitalis slowly, particularly in the first 24 hr.

5. Electrolyte disturbances (especially potassium depletion) produced by concurrent mercurial or thiazide diuresis predispose to digitalis toxicity.

6. Digitalis preparations vary in their rate of dissipation, duration of action, and cumulative effect, so that toxicity may develop more easily with slowly dissipated preparations (digitoxin, digitalis leaf) than with rapidly excreted preparations (digoxin, gitalin). Similarly, the duration of toxic signs, when they develop, varies with the rate of dissipation of the drug. On the other hand, a purified glycoside such as digitoxin, with constancy of absorption and excretion, should cause fewer toxic reactions if the dose is carefully regulated. In the past, toxic reactions with digitoxin often were attributable to the recommended maintenance dose (0.2 mg), which was too large for most patients.

SYMPTOMS AND SIGNS OF DIGITALIS TOXICITY. Allergic reactions and idiosyncrasy to digitalis may occur but are rare. They are manifested by skin eruptions, gastrointestinal disturbances, and eosinophilia. In most cases, reactions are due to toxic effects from overdosage.

Gastrointestinal Symptoms. Loss of appetite and nausea are the early symptoms, followed

renal tubular function is unimpaired in congestive failure, except in terminal failure and in severe ischemic states, where tubular necrosis may occur. Diuretic agents counteract or block the physiologic functions of the proximal and distal tubules involved in the active reabsorption and conservation of sodium and chloride and the passive reabsorption of water, which are enhanced in congestive heart failure

In addition to their primary renal effect, diuretic agents may also favorably influence myocardial function by increasing the cardiac output and reducing venous, atrial, and ventricular diastolic pressures. With the exception of the *xanthines*, however, this results from the increased diuresis of salt and water rather than from a direct effect on cardiac output or renal blood flow The increased diuresis reduces the extracellular and total blood volumes and leads to redistribution of blood from the engorged veins and capillary spaces, thereby increasing the cardiac output The elimination of edema in the lungs, pleural spaces, liver, and peripheral tissues leads to decreased dyspnea, improved ventilatory and hepatic functions, and progressive weight reduction

Types of Diuretics. There are at least six major types of synthetic organic compounds, with different pharmacologic actions, that have wide clinical application as diuretic agents at present. Their intelligent use, alone, alternately or combined, and supplemented with rest, dietary sodium regulation, and digitalization, will result in successful management of most patients with heart failure. They are (1) organomercurials (block proximal tubular reabsorption of sodium), (2) xanthines (increase renal blood flow), (3) pyrimidines, thiouracils (block tubular reabsorption), (4) triazines (block tubular reabsorption of sodium and water), (5) sulfonamides. (*a*) carbonic anhydrase inhibitors (block hydrogen-sodium exchange in distal tubules), (*b*) thiazide derivatives (block proximal and distal tubular reabsorption of sodium and chloride), (6) synthetic steroids, spirolactones (aldosterone inhibitors).

Organomercurials. The organic mercurial compounds, the most widely used diuretic agents, are the most potent and safest for parenteral use They consist of approximately 40 mg Hg per 1 ml solution, combined either with 30 to 50 mg theophylline compound or sodium thioglycollate per milliliter The latter substances act as a carrier of the mercury ions, increase their solubility, stabilize the solutions, increase local absorption, and reduce local irritation After intramuscular or subcutaneous administration, absorption is generally complete in 1 hr Approximately 30 to 40 per cent of the mercury is excreted within 3 hr and 85 to 90 per cent within 24 hr. The prompt liberation of the mercury ion within the renal cortex accounts for the diuretic activity, for the excretion rates of mercury and sodium ions parallel each other. The mercury ions block the enzyme transport systems for reabsorption of sodium and chloride in the proximal renal tubules, producing a hypotonic urine with increase of free water as well as of sodium and chloride Recent studies suggest that reabsorption of sodium and water in the distal tubules is also blocked by mercury. Potassium excretion is slightly but not significantly increased and may be decreased by suppression of tubular secretion of potassium, minimizing the danger of potassium depletion. The diuretic effect is dependent on the availability of chloride and water, and is diminished in hypochloremia.

The prompt excretion of most of the mercury ion within 24 hr permits frequent injections if renal function is normal, even daily ones when indicated When absorption of the mercurial is delayed by severe heart failure or massive local edema, the diuretic response is decreased. Also, in the presence of renal insufficiency, the decreased rate of excretion may lead to mercury retention in the kidneys and, if repeated injections are given, toxic damage of the tubules may occur Severe electrolyte disturbances (hypopotassemia and hyponatremia) do not occur except in patients with advanced heart disease requiring very frequent injections of large doses. There are several good commercial preparations available: meralluride (Mercuhydrin), mercurophylline (Mercuzanthin), mersalyl (Salyrgan Theophylline), mercumatilin (Cumertilin), mercaptomerin (Thiomerin), and merethoxylline procaine (Dicurin). All six preparations are approximately equal in clinical effectiveness and are well absorbed. Mercaptomerin and Dicurin procaine are claimed to have the added advantage of lower toxicity and less irritation when given subcutaneously, but the former is about two-thirds as potent as meralluride.

INDICATIONS AND METHODS OF ADMINISTRATION. Despite the availability of the oral thiazide derivates, the mercurials have retained their importance in the treatment of acute heart failure, in acute emergencies (such as pulmonary edema), and in severe chronic edema These two classes of diuretics (mercurials and thiazides) are not mutually exclusive.

drug may lead to *serious toxicity* if he is overdigitalized. The acetyl-strophanthidin test may be of help in such a case.

Under continuous electrocardiographic monitoring, the patient is given a small intravenous dose (0.1 mg) of this rapidly acting glycoside every 5 to 10 min for a total dose of 0.5 mg. The drug is discontinued if any signs of increased myocardial irritability (premature beats) or conduction disturbance appears. If digitalis toxicity is present, these signs will appear in a few minutes. The test has been of value but may be dangerous and should be applied with caution. A potassium solution should be available for intravenous use in case of severe arrhythmia following the test.

TREATMENT OF DIGITALIS TOXICITY

1. The drug must be stopped immediately until all signs of toxicity have disappeared. This interval may range from 3 to 15 days, depending on the type and dosage of the preparation given.

2. If possible, any potent oral diuretics should also be discontinued; their use may have predisposed to the digitalis toxicity. In severe heart failure, where it would be undesirable to stop the diuretics, one should resort to agents that have less potassium-depleting action, such as mercurials, and should supplement the diuretic therapy with large doses of potassium salts (5 Gm potassium chloride in divided doses on day of and day after the injection).

3. When there is severe nausea and vomiting, the use of bismuth subcarbonate (30 mg) or cocaine (30 mg) by mouth may be of help as local sedatives. If the patient is dehydrated from vomiting and diarrhea, parenteral infusion of glucose and fluids is indicated.

4. *The potassium salts* are valuable agents in all cases of digitalis toxicity associated with myocardial irritability. Potassium salts decrease the myocardial effects of digitalis and are particularly valuable in the early stages of digitalis toxicity. If the patient is not nauseated, large oral doses should be given (5 to 7.5 Gm daily in divided doses). Giving the salt in chilled fruit juice may diminish gastric irritation. In nausea and vomiting, or severe toxicity, or in *acute emergencies*, such as severe paroxysmal tachycardia, intravenous administration is necessary, using a solution of 5.0 Gm potassium chloride per liter of 5 per cent glucose in water. The infusion is given at a fairly rapid rate (4 ml/min) until the arrhythmia stops. Generally, 300 to 500 ml solution (40 mEq of potassium chloride) is necessary for a therapeutic effect. Potassium therapy should be given with caution in the presence of renal insufficiency.

5. Arrhythmias not responding to potassium therapy should be treated with *procaine amide* orally if possible (1.0 Gm initially and 0.5 Gm every 4 to 6 hr) or parenterally (1.0 Gm intramuscularly or by slow intravenous infusion giving 50 to 100 mg every 2 min).

6. In the presence of SA and AV conduction disturbances, the use of potassium salts and procaine amide may be harmful because of their myocardial depressant effects. In such cases, repeated doses of *atropine sulfate* (0.6 mg orally or parenterally) and of *isoproterenol* (5 to 10 mg sublingually or 0.1 to 0.2 mg intramuscularly) may be beneficial.

7. *Chelating agents* may be of value by lowering the blood calcium, which accentuates the effects of digitalis. This treatment has been used to abolish serious cardiac arrhythmia, particularly frequent ectopic beats and atrial and ventricular tachycardia. Dramatic effects may occur following a rapid intravenous infusion of *sodium versenate* (Na EDTA), using a solution of 3 Gm in 300 ml fluid. Although the effects may be transient, this therapy may be useful in emergencies.

DIURETIC THERAPY

The introduction of new potent oral diuretics in the past decade has advanced the clinical importance and effectiveness of diuretic therapy for heart failure.[a] Such diuretics exert their primary action not on the impaired myocardial function but on the renal system, and reverse the process which led to excessive retention of sodium and water responsible for the edema.

The renal adjustments to the decreased cardiac output and reduced renal blood flow in congestive failure include a *decreased glomerular filtration rate*, which is the primary disturbance, and an *increased tubular reabsorption* of sodium and water, which is secondary. The tubular retention of sodium and water is the most powerful process; it is enhanced by hypothalamic reflexes resulting in increased secretion of antidiuretic hormone and by increased blood content of *aldosterone* (partly as a result of decreased inactivation in the congested liver). Recent studies have indicated that

[a] See Part 21, Chap. 9. *Editor.*

is to enhance diuresis by elevating serum chloride levels to 100 mEq/liter or more and urinary chlorides to 40 mEq/liter or more

Ammonium chloride is an effective agent for increasing the level of serum and urine chloride ions The chloride is substituted for carbonic acid in the kidneys, sodium is excreted with the chloride and carbonic acid is retained. The intracellular acidosis and acid urine (pH 5) are temporary, however, and are overcome by increased ammonia production in the kidney, so that in a few days the diuretic effect is gone Large doses are required, ranging from 6 to 10 Gm daily in divided doses (containing 120 to 200 mEq chloride) Although ammonium chloride is tolerated by most patients, gastric irritation (anorexia and nausea) often develops Enteric-coated tablets (1 Gm) may reduce gastric irritation but occasionally are not well absorbed. The drug is used intermittently for 3 or 4 days prior to a mercurial injection and then discontinued temporarily to avoid severe acidosis

Calcium chloride is not well tolerated orally, either, and produces gastric irritation in the required dosage It can be given intravenously in hypochloremia, in doses of 10 ml of the 25 per cent solution several times daily

The organic chlorides, *L-lysine and L-arginine monohydrochloride*, recently have received extensive trial and have been found to be more palatable and better absorbed, producing only occasional diarrhea and abdominal cramps There is less danger of liver toxicity with these agents than with ammonium salts Large doses (20 to 40 Gm daily) are required to deliver an adequate amount of chloride to the serum and kidneys These chlorides are given in four divided doses with cold fruit juices or milk A dose of 40 Gm contains approximately 200 mEq chloride, which in most cases is sufficient to produce adequate chloruresis, with a rise in the urinary chloride level to 40 mEq or more when given for several days prior to a mercurial injection In chronic cardiac edema resistant to mercurial therapy, a daily intravenous infusion of L-arginine monohydrochloride (42 Gm/500 ml) for 1 to 3 days, then combined with a daily mercurial injection for 3 days, has been reported to be more successful than oral therapy in producing hyperchloremia and restoration of responsiveness to the mercurial

Potassium chloride administration, in addition to providing chloride ions, may correct potassium deficiency, which is another cause of decreased response to mercurials Correction of hypopotassemic alkalosis resulting from previous excessive diuresis or severe heart failure is necessary to restore responsiveness to diuretics and decrease the danger of digitalis toxicity

Acetazolamide, alone or in combination with ammonium chloride, can also produce hyperchloremic acidosis and potentiate mercurial diuresis. It is given in doses of 500 mg daily for several days and discontinued 24 hr before the mercurial injection so as to avoid an antagonistic effect.

ORAL ORGANOMERCURIALS Prior to the availability of the thiazide agents, the most potent oral diuretics were the organomercurials, chlormerodrin (Neohydrin), and mercumatilin (Cumertilin). They were widely used for long-term maintenance therapy after the acute heart failure had been controlled with parenteral mercurials and digitalis. Clinical experience up to 1957 (Evans) indicated that the condition of many patients could be controlled with the oral preparations as well as with frequent injections of meralluride

The effective dose ranges between two and six tablets daily in divided doses, and in severe cases up to eight tablets Each tablet, containing 18 mg of the organomercurial, is equivalent to approximately 10 mg organic mercury, so that the average daily effective dose contains 40 to 48 mg Hg. However, only 5 to 10 per cent of the ingested mercury is absorbed and excreted, causing uncertain diuretic effects in some cases Unlike the effect of the carbonic anhydrase inhibitors and the thiouracils, the diuresis is continuous even on long-term administration

Strict attention must be paid to possible side effects and signs of mercurialism, which may occur not infrequently. These include metallic taste, nausea, abdominal cramps, gingivitis, and colitis Patients with signs of cardiac decompensation apparently tolerate the drug better than those who are edema-free Side effects are rare on a dose of three tablets daily or less Occasionally, even reducing the dose below this level does not eliminate gastrointestinal intolerance The other toxic effects and contraindications are the same as those listed for the parenteral mercurials.

The oral organomercurials represent a safe and effective method for maintaining continuous and uniform diuresis (Griffith) Although their use has been largely supplanted by the newer oral thiazide derivatives, they should not be discarded, for they still have an important place in long-term maintenance therapy in selected patients Since their pharmacologic action is mediated through different enzyme systems and their electrolyte excretion patterns differ, the use of these preparations alternately or in combination may be more effective than either one used alone When excessive potas-

Their combined or alternate use is necessary for successful therapy in most cases of severe edema.

The following applications of parenteral mercurial therapy are of value:

1. In *acute heart failure* of moderate to severe intensity, mercurial diuretic therapy should be instituted simultaneously with other measures, such as rest, diet, digitalization, oxygen therapy, etc. An intramuscular injection of 1.5 to 2.0 ml is given at once and may be repeated the next day. Subsequent doses are given every 2 to 4 days, depending on the severity and duration of the congestive symptoms and the diuretic response to each injection. Not more than 2 ml should be given in one dose; some patients respond well to only 1.0 or 1.5 ml. The intervals between injections should be *timed to allow complete excretion of the mercury* and to avoid excessive electrolyte depletion. The weight loss is a good indication of the diuretic response and should serve as a guide to frequency of repeated injections. A 24-hr weight loss of over 5 lb is undesirable. When a "relatively dry" weight is achieved (when the weight curve shows a plateau), the frequency of injection is diminished or the drug may be supplanted by an oral diuretic. Periodic determinations of serum electrolytes are useful to detect excessive depletion when frequent *injections are given*.

2. In *chronic congestive heart failure* with recurrent edema and serous effusions, mercurial injections are usually required regularly. Although such maintenance therapy has been partially, or in some cases completely, supplanted by the newer oral chlorothiazide derivatives, many patients cannot be maintained edema-free or in a comfortable state without additional parenteral therapy. In conjunction with oral therapy, 1- to 2-ml doses can be injected at intervals ranging from twice weekly to *every 2 to 4 weeks*.

3. Parenteral mercurial therapy is preferable in patients with congested gastrointestinal mucosa, nausea or vomiting, gastric ulcer, or gastritis, who cannot tolerate or absorb oral diuretics.

4. In *recurrent acute left ventricular failure* with paroxysmal nocturnal dyspnea or pulmonary edema, an excellent prophylactic effect can be obtained by a mercurial injection. Such an impending attack, heralded by moderate weight gain, cough, or dyspnea, may be more effectively prevented by a *parenteral mercurial* injection, which acts promptly, than by an oral diuretic which is more slowly absorbed.

5. The intravenous route is rarely indicated except in emergency *situations, such as acute pulmonary* edema or paroxysmal dyspnea, where the advantage of a more rapid response outweighs the possible dangers of toxic reactions. *In such cases*, the mercurial may be combined with aminophylline to relieve bronchospasm and increase cardiac output.

MEASURES TO ENHANCE POTENCY OF MERCURIAL DIURETICS. The effectiveness of mercurial diuresis is enhanced by (1) increased renal blood flow, (2) acidosis or increased pH, and (3) hyperchloremia.

Measures to Increase Renal Blood Flow. The two important measures are *bed rest* and use of *xanthine drugs*. *As already discussed, the cardiac* output and renal blood flow are increased by resting in the recumbent position. Resting for several hours after a mercurial injection may therefore potentiate its effect. In cases where there is massive dependent edema with induration of the tissues, the response to mercurial therapy may be enhanced by *elevation and elastic bandaging* of the edematous lower limbs. This procedure increases the plasma volume and makes more extracellular *fluid available to the kidneys for diuresis*. It should be applied *cautiously after the diuretic* response to the mercurial has begun, to avoid overloading of the venous and pulmonary vessels, and pulmonary edema. Similarly, the xanthine drugs (aminophylline, theophylline) produce a transitory increase in cardiac output. A parenteral injection of *aminophylline* (0.25 to 0.5 Gm) 1 to 3 hr after a mercurial injection may increase renal blood flow and glomerular filtration rate and the diuretic response.

effective diuresis. The acidifying salts potentiate diuresis by producing intracellular tubular acidosis and elevating the serum chloride level, thereby increasing the availability of chloride *for urinary* excretion. The production of hyperchloremic acidosis, by lowering the pH within the renal tubules, facilitates the liberation of mercury ions and enhances the blocking effect on the tubular reabsorption of sodium.

Several types of chloride and acidifying salt have been used *to attain* this effect, including ammonium chloride, calcium chloride, L-lysine and L-arginine monohydrochloride, and acetazolamide. Supplementing mercurial therapy with these acidifying and chloride preparations has become an important clinical measure when the diuretic response to mercurials becomes inadequate and when there is evidence of hypochloremic alkalosis owing to insufficient chloride intake or excessive chloride loss from prolonged diuretic therapy. A poor response to mercurials occurs when the serum chloride level falls below 90 mEq/liter and urinary chlorides fall to 10 mEq/liter or less. The aim of pretreatment with acidifying salts and chlorides

is to enhance diuresis by elevating serum chloride levels to 100 mEq/liter or more and urinary chlorides to 40 mEq/liter or more.

Ammonium chloride is an effective agent for increasing the level of serum and urine chloride ions. The chloride is substituted for carbonic acid in the kidneys, sodium is excreted with the chloride and carbonic acid is retained. The intracellular acidosis and acid urine (pH 5) are temporary, however, and are overcome by increased ammonia production in the kidney, so that in a few days the diuretic effect is gone. Large doses are required, ranging from 6 to 10 Gm daily in divided doses (containing 120 to 200 mEq chloride). Although ammonium chloride is tolerated by most patients, gastric irritation (anorexia and nausea) often develops. Enteric-coated tablets (1 Gm) may reduce gastric irritation but occasionally are not well absorbed. The drug is used intermittently for 3 or 4 days prior to a mercurial injection and then discontinued temporarily to avoid severe acidosis.

Calcium chloride is not well tolerated orally, either, and produces gastric irritation in the required dosage. It can be given intravenously in hypochloremia, in doses of 10 ml of the 25 per cent solution several times daily.

The organic chlorides, L-lysine and L-arginine monohydrochloride, recently have received extensive trial and have been found to be more palatable and better absorbed, producing only occasional diarrhea and abdominal cramps. There is less danger of liver toxicity with these agents than with ammonium salts. Large doses (20 to 40 Gm daily) are required to deliver an adequate amount of chloride to the serum and kidneys. These chlorides are given in four divided doses with cold fruit juices or milk. A dose of 40 Gm contains approximately 200 mEq chloride, which in most cases is sufficient to produce adequate chloruresis, with a rise in the urinary chloride level to 40 mEq or more when given for several days prior to a mercurial injection. In chronic cardiac edema resistant to mercurial therapy, a daily intravenous infusion of L-arginine monohydrochloride (42 Gm/500 ml) for 1 to 3 days, then combined with a daily mercurial injection for 3 days, has been reported to be more successful than oral therapy in producing hyperchloremia and restoration of responsiveness to the mercurial.

Potassium chloride administration, in addition to providing chloride ions, may correct potassium deficiency, which is another cause of decreased response to mercurials. Correction of hypopotassemic alkalosis resulting from previous excessive diuresis or severe heart failure is necessary to restore responsiveness to diuretics and decrease the danger of digitalis toxicity.

Acetazolamide, alone or in combination with ammonium chloride, can also produce hyperchloremic acidosis and potentiate mercurial diuresis. It is given in doses of 500 mg daily for several days and discontinued 24 hr before the mercurial injection so as to avoid an antagonistic effect.

ORAL ORGANOMERCURIALS. Prior to the availability of the thiazide agents, the most potent oral diuretics were the organomercurials, chlormerodrin (Neohydrin), and mercumatilin (Cumertilin). They were widely used for long-term maintenance therapy after the acute heart failure had been controlled with parenteral mercurials and digitalis. Clinical experience up to 1957 (Evans) indicated that the condition of many patients could be controlled with the oral preparations as well as with frequent injections of meralluride.

The effective dose ranges between two and six tablets daily in divided doses, and in severe cases up to eight tablets. Each tablet, containing 18 mg of the organomercurial, is equivalent to approximately 10 mg organic mercury, so that the average daily effective dose contains 40 to 48 mg Hg. However, only 5 to 10 per cent of the ingested mercury is absorbed and excreted, causing uncertain diuretic effects in some cases. Unlike the effect of the carbonic anhydrase inhibitors and the thiouracils, the diuresis is continuous even on long-term administration.

Strict attention must be paid to possible side effects and signs of mercurialism, which may occur not infrequently. These include metallic taste, nausea, abdominal cramps, gingivitis, and colitis. Patients with signs of cardiac decompensation apparently tolerate the drug better than those who are edema-free. Side effects are rare on a dose of three tablets daily or less. Occasionally, even reducing the dose below this level does not eliminate gastrointestinal intolerance. The other toxic effects and contraindications are the same as those listed for the parenteral mercurials.

The oral organomercurials represent a safe and effective method for maintaining continuous and uniform diuresis (Griffith). Although their use has been largely supplanted by the newer oral thiazide derivatives, they should not be discarded, for they still have an important place in long-term maintenance therapy in selected patients. Since their pharmacologic action is mediated through different enzyme systems and their electrolyte excretion patterns differ, the use of these preparations alternately or in combination may be more effective than either one used alone. When excessive potas-

sium excretion occurs with the thiazides, or serious side effects, diuretic therapy can be maintained by switching to an oral organomercurial. This may obviate the use of frequent mercurial injections in ambulatory patients.

Xanthine Drugs. The xanthine agents (theophylline derivatives) act as mild transitory diuretics by their effect on renal hemodynamics. The increase in cardiac output and renal blood flow causes an increase in glomerular filtration rate and makes more filtrate and solute available for tubular excretion. Although there may be a direct tubular effect as well, the primary diuretic action of the xanthines is mediated through their cardiorenal hemodynamic effects There is little danger of renal damage or electrolyte disturbances The xanthines are not sufficiently potent to be used as primary diuretic agents, but the following applications may have clinical value for adjuvant therapy:

Most available parenteral preparations are combinations of mercury and a theophylline agent. The latter, by its effect on glomerular filtration, potentiates the diuretic effect of the mercurial.

A further potentiating effect can be produced by an additional intravenous injection of *aminophylline* (theophylline-ethylenediamine) at the height of the mercurial diuresis (2 to 3 hr after the mercurial injection). Studies have shown a significant increase in renal blood flow, glomerular filtration rate, and sodium excretion by this method To avoid hypotension due to peripheral vasodilatation, the intravenous injection must be given slowly, preferably as a slow drip of 0 5 mg in 250 ml of 5 per cent glucose in water. It is generally given to patients with chronic failure responding poorly to the mercurials Rectal administration in the form of *aminophylline suppositories* (0 5 Gm) or infusion of a solution (0 5 to 1 0 Gm in 100 ml) may give good blood levels but absorption is slower.

Aminophylline intravenously may be used in the emergency treatment of acute pulmonary edema, in which a bronchospastic factor may be important The bronchodilator and cardiac stimulating effects may help to abort the acute attack if used early. Here, too, the injection must be given slowly to avoid hypotensive effects

Oral administration of the xanthines produces only mild transient diuresis unless large doses are used (up to 1 2 Gm daily in divided doses). Such dosage may produce side effects such as nausea, vomiting, and nervousness Several commercial preparations, including *Elixophylline* (15 ml), *Choledyl* (0 2 Gm), and *Aminophylline Dura-Tab* (0.3 Gm), have been introduced in an attempt to minimize these side effects. It is claimed that these agents not only have a diuretic effect but may alleviate episodes of dyspnea They can be used intermittently in mild cases of heart failure, particularly in alternation with the more potent agents to minimize the danger of electrolyte depletion.

Pyrimidines or Cytosine Diuretics (Thiouracils). The *aminouracils* (aminometradine and aminosisometradine), which resemble the xanthines in structure, are mildly potent, oral, nonmercurial diuretic agents. The diuresis (increased excretion of sodium, chlorides, and water) is probably effected by a blocking action on tubular reabsorption. Because of their relatively mild potency and their occasional gastric and other side effects with therapeutic doses (nausea), they have been largely replaced by the more potent thiazide derivatives. However, they may occasionally find a useful place in the therapy of mild heart failure or edema states, especially when the mercurials and thiazides cannot be safely administered or do not produce an adequate response. There are no contraindications to their use, even in the presence of liver or renal insufficiency.

The therapeutic dosage of *aminometradine* (*Rolicton*) ranges between 800 to 1,800 mg daily Starting with 200 mg with each meal, the dosage is gradually increased to 400 to 600 mg per dose until optimum diuresis is achieved; then the dose may be halved. The agent is used intermittently for several-day periods to avoid drug tolerance and loss of potency.

Triazine Diuretics. Chlorazanil (Daquin), a triazine compound, is a mildly potent diuretic with low toxicity, which increases the excretion of sodium chloride and water. The water excretion is relatively greater than that of the electrolytes. Potassium excretion is unchanged or diminished Diuretic action is due to (1) a blocking action on tubular electrolyte reabsorption which differs from that exerted by the mercurials and chlorothiazide, and (2) an antagonistic effect on certain steroid hormones involved in fluid retention. Although it is not much more potent than acetazolamide, it has

the advantage of continued effectiveness on prolonged administration.

A daily dose of 300 mg for several days produces a continuous diuretic response, and if necessary may be increased to 600 mg in divided doses for short-term periods. Prolonged administration of over 300 mg daily, however, may reduce the glomerular filtration rate with impaired renal function (rise in blood urea nitrogen and creatinine, depressed phenolsulfonphthalein excretion). The drug can be used as a supplement or as an alternate to the mercurials or thiazides.

Carbonic Anhydrase Inhibitors. There are two available sulfonamide derivatives, *acetazolamide* (Diamox) and *ethoxazolamide* (Cardrase), which act as mildly potent but nontoxic diuretics. They inhibit sodium reabsorption in the distal tubules by inhibiting the action of carbonic anhydrase, which is involved in the dissociation of carbonic acid to form free H ions. The drug blocks the exchange of hydrogen and sodium ions in the tubular cells, and the interference with carbonate reabsorption results in increased urinary excretion of sodium bicarbonate and potassium but not of chlorides and causes metabolic acidosis. The anhydrase inhibition and increased diuresis are usually transient, lasting for several days only.

These agents have approximately half the relative potency of the thiazide derivatives and one-quarter the potency of the mercurials, and their effectiveness does not improve with increased dosage. A daily dose of 250 to 500 mg is just as effective as a larger dose. Because of the mild potency and development of refractoriness and loss of diuretic effect after 2 to 4 days, they have been largely replaced for oral therapy by the more potent thiazide derivatives.

There are a few special clinical situations in which they may still find a useful place.

1. They may potentiate the action of mercurial diuretics in refractory edema. The hyperchloremia produced by the carbonic anhydrase inhibitors may help to restore responsiveness to a mercurial injection. Diamox or Cardrase may be given for 3 days in doses of 250 to 500 mg daily and then discontinued a day prior to the mercurial injection. After at least 2 days the drug may be started again and the cycle repeated.

2. These agents may augment the diuretic effect of the chlorothiazide derivatives and can supplement them when diuretic response is impaired. Here, too, administration is intermittent, the drug being given daily for 2 or 3 days, or on every second or third day, in doses of 250 to 500 mg daily.

3. It has been claimed that in patients with chronic cor pulmonale and excessive carbon dioxide retention, the increased acidosis produced by the carbonic anhydrase inhibitors may be beneficial by stimulation of the respiratory center. A relatively large dose of 500 to 750 mg daily for several days is given for this purpose.

Mild side effects may occur with these agents, including drowsiness, nausea, and paresthesias. However, their use is dangerous in the presence of renal insufficiency with acidosis.

Thiazide Derivatives. The recent introduction of *chlorothiazide* and its analogues and derivatives has revolutionized the diuretic therapy of heart failure. Although the mercurials have maintained their primary position in the treatment of acute heart failure and emergencies, the thiazide derivatives are probably more widely used for oral maintenance therapy.

The thiazides resemble in structure the carbonic anhydrase inhibitors, but their major pharmacologic action approaches that of a potent organomercurial. Their diuretic effect is based on inhibition of enzyme transport systems in the proximal and distal renal tubules, producing an excretion pattern similar to that of the mercurials by blocking reabsorption of sodium, chloride, and water, but with a significantly greater increase in potassium excretion. These agents produce no significant effects on renal hemodynamics. Their potency is considerable, being equivalent to that of the mercurials, and toxicity is negligible. They are well tolerated orally, with few side effects. Following a therapeutic dose, diuresis begins within 1 hr and reaches a peak effect in about 6 hr. The total effect lasts for about 18 hr, with a range of 12 to 24 hr. Diuretic potency does not diminish with prolonged administration. Saluresis continues with repeated doses until the excess sodium stores and retained fluids are excreted. In the absence of sodium retention the level of urinary excretion of sodium returns to normal in several days.

Since chlorothiazide was introduced in 1957, numerous analogues and derivatives have been developed (Table 18-24) with the aim of increasing the diuretic potency and of improving the electrolyte excretion pattern, particularly with respect to potassium loss. It can be seen in Table 18-24 that the newer agents are given in smaller dosage than chlorothiazide, and, milligram for milligram, are more potent (ten to one hundred times). However, at maximum effective dosage, all the agents produce a similar diuresis, with increased sodium excretion and weight loss, and with the same bene-

sium excretion occurs with the thiazides, or serious side effects, diuretic therapy can be maintained by switching to an oral organomercurial. This may obviate the use of frequent mercurial injections in ambulatory patients.

Xanthine Drugs. The xanthine agents (theophylline derivatives) act as mild transitory diuretics by their effect on renal hemodynamics. The increase in cardiac output and renal blood flow causes an increase in glomerular filtration rate and makes more filtrate and solute available for tubular excretion. Although there may be a direct tubular effect as well, the primary diuretic action of the xanthines is mediated through their cardiorenal hemodynamic effects. There is little danger of renal damage or electrolyte disturbances. *The xanthines are not sufficiently potent to be used as primary diuretic agents, but the following applications may have clinical value for adjuvant therapy:*

Most available parenteral preparations are combinations of mercury and a theophylline agent. The latter, by its effect on glomerular filtration, potentiates the diuretic effect of the mercurial.

A further potentiating effect can be produced by an additional intravenous injection of *aminophylline* (theophylline-ethylenediamine) at the height of the mercurial diuresis (2 to 3 hr after the mercurial injection). Studies have shown a significant increase in renal blood flow, glomerular filtration rate, and sodium excretion by this method. To avoid hypotension due to peripheral vasodilatation, the intravenous injection must be given slowly, preferably as a slow drip of 0.5 mg in 250 ml of 5 per cent glucose in water. It is generally given to patients with chronic failure responding poorly to the mercurials. Rectal administration in the form of *aminophylline suppositories* (0.5 Gm) or infusion of a solution (0.5 to 1.0 Gm in 100 ml) may give good blood levels but absorption is slower.

Aminophylline intravenously may be used in the emergency treatment of acute pulmonary edema, in which a bronchospastic factor may be important. The bronchodilator and cardiac stimulating effects may help to abort the acute attack if used early. Here, too, the injection must be given slowly to avoid hypotensive effects.

Oral administration of the xanthines produces only mild transient diuresis unless large doses are used (up to 1.2 Gm daily in divided doses). Such dosage may produce side effects such as nausea, vomiting, and nervousness. Several commercial preparations, including *Elixophylline* (15 ml), *Choledyl* (0.2 Gm), and *Aminophylline Dura-Tab* (0.3 Gm), have been introduced in an attempt to minimize these side effects. It is claimed that these agents not only have a diuretic effect but may alleviate episodes of dyspnea. They can be used intermittently in mild cases of heart failure, particularly in alternation with the more potent agents to minimize the danger of electrolyte depletion.

Pyrimidines or Cytosine Diuretics (Thiouracils). *The aminouracils* (aminometradine and aminosisometradine), which resemble the xanthines *in structure, are mildly potent, oral, nonmercurial diuretic agents.* The diuresis (increased *excretion of sodium, chlorides,* and water) is probably effected by a blocking action on *tubular reabsorption.* Because of their relatively mild potency and their occasional gastric and other *side effects* with therapeutic doses (nausea), they have been largely replaced by the more *potent thiazide derivatives.* However, they may occasionally find a useful place in the therapy of *mild heart failure* or edema states, especially when the mercurials and thiazides cannot be safely administered or do not produce an adequate response. There are no contraindications to their use, even in the presence of liver or renal insufficiency.

The therapeutic dosage of *aminometradine* (*Rolicton*) ranges between 800 to 1,800 mg daily. Starting with 200 mg with each meal, the dosage is gradually increased to 400 to 600 mg per dose until optimum diuresis is achieved, then the dose may be halved. The agent is used intermittently *for several-day* periods to avoid drug tolerance and loss of potency.

Triazine Diuretics. *Chlorazanil* (*Daquin*), a triazine compound, *is a mildly* potent diuretic with low toxicity, which increases the excretion of sodium *chloride and* water. The water excretion is relatively greater than that of the electrolytes. *Potassium excretion* is unchanged or diminished. Diuretic action is due to (1) a blocking action *on tubular* electrolyte reabsorption which differs from that exerted by the *mercurials and chlorothiazide*, and (2) an antagonistic effect on certain steroid hormones *involved in fluid retention.* Although it is not much more potent than acetazolamide, it has

the advantage of continued effectiveness on prolonged administration

A daily dose of 300 mg for several days produces a continuous diuretic response, and if necessary may be increased to 600 mg in divided doses for short-term periods. Prolonged administration of over 300 mg daily, however, may reduce the glomerular filtration rate with impaired renal function (rise in blood urea nitrogen and creatinine, depressed phenolsulfonphthalein excretion). The drug can be used as a supplement or as an alternate to the mercurials or thiazides.

Carbonic Anhydrase Inhibitors. There are two available sulfonamide derivatives, *acetazoleamide* (*Diamox*) and *ethoxazolamide* (*Cardrase*), which act as mildly potent but nontoxic diuretics They inhibit sodium reabsorption in the distal tubules by inhibiting the action of carbonic anhydrase, which is involved in the dissociation of carbonic acid to form free H ions The drug blocks the exchange of hydrogen and sodium ions in the tubular cells, and the interference with carbonate reabsorption results in increased urinary excretion of sodium bicarbonate and potassium but not of chlorides and causes metabolic acidosis The anhydrase inhibition and increased diuresis are usually *transient, lasting for several days only*

These agents have approximately half the relative potency of the thiazide derivatives and one-quarter the potency of the mercurials, and their effectiveness does not improve with increased dosage. A daily dose of 250 to 500 mg is just as *effective as a larger dose* Because of the mild potency and development of refractoriness and loss of diuretic effect after 2 to 4 days, they have been largely replaced for oral therapy by the more potent thiazide derivatives

There are a few special clinical situations in which they may still find a useful place

1 They may potentiate the action of mercurial diuretics in refractory edema The hyperchloremia produced by the carbonic anhydrase inhibitors may help to restore responsiveness to a mercurial injection Diamox or Cardrase may be given for 3 days in doses of 250 to 500 mg daily and then discontinued a day prior to the mercurial injection After at least 2 days the drug may be started again and the cycle repeated

2 These agents may augment the diuretic effect of the chlorothiazide derivatives and can supplement them when diuretic response is impaired. Here, too, administration is intermittent, the drug being given daily for 2 or 3 days, or on every second or third day, in doses of 250 to 500 mg daily.

3 It has been claimed that in patients with chronic cor pulmonale and excessive carbon dioxide retention, the increased acidosis produced by the carbonic anhydrase inhibitors may be beneficial by stimulation of the respiratory center. A relatively large dose of 500 to 750 mg daily for several days is given for this purpose

Mild side effects may occur with these agents, including drowsiness, nausea, and paresthesias. However, their use is dangerous in the presence of renal insufficiency with acidosis.

Thiazide Derivatives. The recent introduction of *chlorothiazide* and its analogues and derivatives has revolutionized the diuretic therapy of heart failure. Although the mercurials have maintained their primary position in the treatment of acute heart failure and emergencies, the thiazide derivatives are probably more widely used for oral maintenance therapy.

The thiazides resemble in structure the carbonic anhydrase inhibitors, but their major pharmacologic action approaches that of a potent organomercurial. *Their diuretic effect is based on inhibition of enzyme transport systems in the proximal and distal renal tubules*, producing an excretion pattern similar to that of the mercurials by blocking reabsorption of sodium, chloride, and water, but with a significantly greater increase in potassium excretion. These agents produce no significant effects on renal hemodynamics. Their potency is considerable, being equivalent to that of the mercurials, and toxicity is negligible. They are well tolerated orally, with few side effects Following a therapeutic dose, diuresis begins within 1 hr and reaches a peak effect in about 8 hr The total effect lasts for about 18 hr, with a range of 12 to 24 hr. Diuretic potency does not diminish with prolonged administration Saluresis continues with repeated doses until the excess sodium stores and retained fluids are excreted In the absence of sodium retention the level of urinary excretion of sodium returns to normal in several days

Since chlorothiazide was introduced in 1957, numerous analogues and derivatives have been developed (Table 18-24) with the aim of increasing the diuretic potency and of improving the electrolyte excretion pattern, particularly with respect to potassium loss. It can be seen in Table 18-24 that the newer agents are given in smaller dosage than chlorothiazide, and, milligram for milligram, are more potent (ten to one hundred times). However, at maximum effective dosage, all the agents produce a similar diuresis, with increased sodium excretion and weight loss, and with the same bene-

ficial effect on edema and other signs of heart failure. The electrolyte excretion pattern seems to be more favorable with the newer agents, particularly the benzylflumethiazide analogues, and chlorphthalidolone, a phthalimidine rather than a thiazide derivative. The sodium to potassium excretion ratio appears to be greater, with less potassium excretion without loss of saluretic and chloruretic effect. However, *potassium depletion* remains an important factor with these agents, particularly following prolonged administration for protracted edema.

CLINICAL APPLICATIONS. The thiazide agents are indicated in all types and in all grades of heart failure. In severe acute failure, it is generally preferable to initiate therapy with injections of a mercurial diuretic daily, or on alternate days for several days. Then, after the main symptoms have been controlled, one can switch to oral therapy with one of the thiazide agents. When the situation is not too acute or urgent, one may start therapy at once with the oral agents. The daily maximum effective dose (Table 18-24) is given in divided doses for the first few days; after a single dose, diuresis may regress after 12 to 18 hr. Also, the diuretic effect is greater with divided doses, every 6 hr, than with one larger daily dose. With all the agents, there is a maximum effective dose above which there is no greater diuretic response. For example, doubling the dose of benzydroflumethiazide from 10 to 20 mg or hydrochlorothiazide from 100 to 200 mg/day *may not significantly increase the 24-hr natriuretic response.* After several days, when edema has diminished and moderate weight loss has been obtained and the weight curve has flattened, the daily dose is reduced to the minimum effective dose required to maintain the weight constant and the patient edema-free. The average maintenance dose (Table 18-24) generally ranges between one-fourth to one-half the dose used in active or initial treatment. If the patient remains edema-free, the dose should be omitted 1 or 2 days each week, to minimize electrolyte disturbances. If signs of edema recur, short intermittent courses of increased doses can be given.

It is important that all the other measures recommended for heart failure be carried out during the stage of active treatment. The indi-

TABLE 18-24 CHARACTERISTICS OF THE THIAZIDE DIURETICS

Thiazide diuretic	*Commercial preparation*	*Potency* *	*Dose, mg*		*Urinary excretion pattern*
			Active treatment	*Maintenance*	
Chlorothiazide	Diuril	0.8	1,000–2,000	250–500	Increased excretion of Na, Cl, and K. Na:K ratio = 3:1. Increased bicarbonate excretion with high doses
Hydrochlorothiazide	Hydrodiuril Esidrix Oretic	1.4	100–200	25–50	Cl excretion greater than Na. Na:K ratio = 5:1
Flumethiazide	Ademol	0.7	1,000–2,000	250–500	Less K excretion at similar dosage
Hydroflumethiazide	Di-Ademil Saluron	1.3	100–200	25–50	Greater Cl excretion than Na. K excretion similar to 3. *Less* bicarbonate excretion
Benzylthiomethyl chlorothiazide (Benzthiazide)	Naclex		100–200	25–50	Na:K ratio more favorable than above. Less bicarbonate excretion
Benzydroflumethiazide	Naturetin	1.8	10–20	2.5–5	Same. Na:K ratio, 7:1
Methylclothiazide	Enduron	1.8	5–10	2.5–5	Same. Na:K ratio, 10:1
Trichlormethiazide	Naqua Metahydrin	1.75	8–16	1–4	Same. Na:K ratio, 6:1
Chlorphthalidolone chlorthalidone	Hygroton	1.8	50	25–50 q.o.d.	Phthalimidine derivative. Excretion pattern same as 8. More prolonged diuresis (over 24 hr)

* Relative to meralluride.

cations for digitalis therapy remain unchanged. Clinical experience has indicated that most patients can be *maintained edema-free* with the combined use of restricted activity, digitalization, and dietary salt restriction. Mercurial injections may be needed periodically if there is recurrence of acute symptoms, but the annoyance of frequent injections is minimized. Also, as previously discussed, rigid restriction *of dietary sodium to 500 mg or less* has become less essential.

With oral daily diuretic therapy, the necessity for using salt-free bread, butter, and milk has diminished. Small amounts of salt can be used in the cooking, depending on the degree *of salt retention and weight gain* observed with *increased salt intake*, and the sodium intake can be gradually increased to 2.0 Gm daily.

TOXIC EFFECTS, PREVENTION AND TREATMENT. As in the case of mercurial diuretics, close observation is essential to detect possible side effects and toxic reactions from the thiazide drugs. This *applies particularly to the* patient on daily maintenance therapy who may not report for reexamination for days, weeks, or even months. The following conditions should be looked for and corrected if present.

Gastrointestinal Irritation. Occasional patients *may develop* nausea, diarrhea, or abdominal cramps. *These symptoms* are aggravated by mucosal congestion in the gastrointestinal tract but may also occur in the absence of visceral congestion. They may be relieved by temporarily discontinuing and then reducing *the dose. Rarely*, the drug has to be discontinued completely.

Skin Eruptions. Pruritus, *paresthesias, and* dermatitis may occur occasionally and may be an indication to discontinue the drug.

Leg Cramps. These may occur, as with any *potent diuretic, when there* is profuse diuresis with excessive loss *of salt. This requires* reducing the size and frequency of the dosage.

Hypotensive Reactions. Occasionally, patients on long-term maintenance therapy may develop orthostatic hypotension with faintness, dizziness, and rarely syncope. These reactions may develop even *when other antihypertensive* drugs have not been administered. In such cases the dosage of all medications must be reduced.

Hyperuricemia. Elevation of serum uric acid levels may occur *occasionally* and is usually asymptomatic. In gouty patients or in those with *latent* gout, it may result in acute exacerbations. If such hyperuricemia is not controlled with *salicylates* and *Probenecid*, the thiazide therapy should be stopped.

Hyperglycemia. Blood sugar levels are occasionally elevated by these drugs. Persons with latent diabetes may develop signs of diabetes (hyperglycemia and glycosuria), and *known diabetic patients may require increase in dosage of insulin or other antidiabetic agents.* Severe diabetic *reactions are rare.*

Renal Damage. The level of blood urea nitrogen (BUN) should be determined periodically in all patients. Mild elevations of blood urea nitrogen may revert to normal *spontaneously* as the failure *improves or with increased* fluid intake. With long-term therapy, however, more persistent elevation of BUN may occur; this is an indication to discontinue the drug. Impaired renal function with *elevated BUN is* rare, and is more likely to develop in patients on severely restricted salt intake with *hyponatremia and hypochloremic alkalosis.* When signs of renal insufficiency and oliguria are present, dietary salt must not be rigidly restricted, and the thiazide drugs should be given with great caution. It would be safer to use intermittent parenteral mercurial therapy rather than continuous therapy with the oral agents.

Electrolyte Depletion. Frequent *serum* electrolyte determinations are indicated in all patients receiving large doses of the thiazide agents for protracted periods. As with the potent mercurial diuretics, severe electrolyte depletion and metabolic imbalance generally *occur in patients with* advanced myocardial disease, protracted *congestive failure*, and deranged cellular electrolyte balance, who have had prolonged and intense diuretic therapy, and in those with previously impaired renal function. The electrolyte disturbances include *hyponatremia*, hypochloremic alkalosis, and *hypopotassemia.*

1. *Hyponatremia.* This is *generally* observed in chronically ill patients with resistant edema and impaired renal function. It is rarely caused *by the* diuretic agent itself. The hyponatremia *is generally* dilutional in type, because of excess water retention, and does not necessarily indicate an excess loss *of sodium, for although* serum sodium is low, the total *body sodium* stores may be increased. This differs from the acute depletional hyponatremia occurring with

restricted salt intake and excessive sodium loss from vigorous diuretic therapy or vomiting. Except in the latter situations, administration of salt solutions is dangerous. Preferably one should discontinue the thiazide drug, restrict fluid intake moderately, and treat with intermittent doses of a mercurial diuretic primed with ammonium chloride or other chloride salt and aminophylline. This may restore a more normal serum sodium level.

2. *Hypochloremic Alkalosis.* This metabolic disturbance is also a manifestation of long-standing heart failure, aggravated by protracted diuretic therapy with chloride-depleting agents. It is an indication to temporarily discontinue thiazide therapy and to carry out the corrective measure for this condition outlined in the section on mercurial diuretics. These measures are essential to restore responsiveness to further diuretic therapy.

3. *Hypopotassemia.* This electrolyte disturbance has become of increasing importance with the ever-increasing use of the potent thiazide agents, which may cause relatively greater potassium excretion than other diuretics. The degree of potassium depletion is related also to the severity of the heart failure, being aggravated by excess aldosterone secretion and reduced sodium excretion Serum potassium levels should be checked in all patients on prolonged therapy. The potassium depletion is less marked with the newer thiadiazine analogues than with chlorothiazide. Despite this, it is desirable to supplement the diuretic therapy with moderate doses of potassium salts, such as potassium chloride (1 to 2 Gm daily) or potassium triplex (5 ml t.i.d) In fact, most of the commercial preparations are now available in a combined tablet with 500 mg potassium chloride, which may be adequate for prophylactic purposes. The diet should be adjusted so as to provide a more liberal sodium and potassium intake High-potassium foods should be included, such as citrus fruits and juices, meat, bran, and milk. When significant hypopotassemia already exists, larger supplemental doses of potassium salts are required and the daily dosage and frequency of administration of the diuretic agent should be reduced.

The two important dangers of severe hypopotassemia are *kidney damage* with impaired renal function and *increased myocardial irritability* The latter may precipitate or aggravate digitalis toxicity in patients on combined digitalis and thiazide therapy. *There appears to be a direct relationship between myocardial concentration of potassium and the dose of digitalis required to produce toxicity.* In acute heart failure, digitalization must proceed more cautiously if the patient is simultaneously receiving large doses of a thiazide drug or other potassium-depleting agent and is excreting increased amounts of urine and electrolytes. Serious *cardiac arrhythmias* may be precipitated by potassium depletion, even before the average toxic range of the digitalis preparation is reached. Similarly, in patients on long-term maintenance therapy with both digitalis and a thiazide agent, strict attention must be paid to dosage of the drugs, dietary potassium and sodium intake, and supplemental potassium administration. In such patients, the minimum rather than the maximum effective maintenance dose of each drug is indicated. The thiazides must be discontinued and oral potassium therapy instituted whenever digitalis toxicity is suspected or there is a significant fall in serum potassium.

When frank digitalis toxicity has developed, larger oral dosage (5 to 7 Gm daily) or intravenous infusion (3 to 4 Gm) of potassium salts becomes necessary, as outlined previously (see Digitalis Toxicity). If continued diuretic therapy is indicated, it would be safer to give intermittent doses of a parenteral mercurial rather than daily doses of a thiazide agent.

Spironolactones. Several years ago, it was observed clinically that the *corticosteroids,* which normally enhance tubular reabsorption of sodium and water and create edema, may exert a paradoxic effect on patients with advanced heart failure and intractable edema by increasing sodium and water excretion (Reimer). Corticosteroid therapy was noted to

filtration rate, inhibition of antidiuretic hormone, and an antagonistic effect on the sodium reabsorption action of aldosterone The latter was considered the most important mechanism.

More recently a new group of *antialdosterone agents* has been introduced, viz, the spironolactones (17-spirolactosteroids). Their use is based on the observation that severe or prolonged congestive failure is associated with a state of secondary *hyperaldosteronism* The ex-

cessive aldosterone excretion increases the reabsorption and retention of sodium and water by the renal tubules, and aggravates the edema state. It has been demonstrated that the spironolactones block the tubular sodium retention and potassium excretion produced by aldosterone. Since the diuretic effect of the spironolactones is mediated by a different mechanism from that of the usual diuretic agents, they should be considered in the treatment of patients with chronic or severe edema not responding well to the usual diuretic regimen.

The available commercial preparation (*Aldactone*), introduced several years ago, has been found to be a useful agent as an adjuvant in the treatment of heart failure, particularly when combined with other therapy. It is available as 100-mg tablets, with a recommended dosage of 300 to 1,200 mg daily (average *100 to 200 mg four times daily*). (*Aldactone A, introduced recently, is available in 25-mg tab*lets, which are equivalent in potency to the 100 mg tablets of Aldactone) Studies during short courses of therapy (7 days) have demonstrated increased urinary output of sodium,

it may be delayed for 1 to 3 days after onset of therapy and then reaches a peak in 2 to 3 days *Drug* tolerance or resistance does not develop with *continued administration* The side effects of the drug are few and mild, such as drowsiness and skin eruptions However, the drug has not been used for sufficiently long periods to indicate its ultimate value and *safety*

CLINICAL APPLICATIONS. *In severe failure re*sistant to mercurials or thiazides, these should be temporarily discontinued, and the patient given 600 to 800 mg spironolactone daily in divided doses A good response is manifested by *increased urinary* excretion and weight loss within 3 to 5 days *of onset of therapy*. The dose can then be reduced to 400 to 600 mg daily for several days or weeks and then replaced by conventional diuretic therapy.

If an inadequate response is observed with increasing doses *of spironolactone* (up to 1,200 mg daily), the therapy is supplemented with an oral thiazide preparation in the usual therapeutic dose or with mercurial injections or both Patients previously resistant to these agents may show a sudden return of responsiveness, with progressive weight *loss and increased* sodium excretion The spironolactone *may* neutralize the *potassium-excreting* effects of these agents, diminishing the dangers of potassium depletion and digitalis toxicity.

In cases of edema refractory to previous intensive therapy, the spironolactone can be added to the diuretic regimen, and the previous measures continued, including the oral chlorothiazide agents, *mercurials, acidifying* and *chloruretic drugs and corticosteroids*. The addition of the spironolactone may produce prompt and gratifying diuresis.

RECAPITULATION OF TREATMENT

The available measures to treat the physiologic disturbances in the heart and kidneys *that are responsible for the manifestations of* heart failure have been discussed. The clinician should be familiar with all of them, so that he can individualize the management of each case, depending upon the type of heart disease present, the precipitating cause of the heart failure, its severity and duration, the type

various pharmacologic agents should vary in cases of mild failure, severe failure, and so-called refractory failure.

Mild Heart Failure. Therapy for mild failure *is as important as for severe heart failure,* since neglect of early *signs of decompensation* may lead subsequently to severe or even irreversible failure. In general, most cases of mild failure can be controlled by restriction of physical stresses, moderate curtailment of salt intake, and slow digitalization followed by minimally *effective maintenance dosage*. As already emphasized, the latter should not be *neglected* in favor of the newer diuretics, since these merely treat the secondary renal manifestations of failure whereas digitalis acts directly on the *impaired* myocardial function to correct the *hemodynamic disturbances*. However, there is no objection to administering *one or more* mercurial injections at the onset or initiating *oral* diuretic therapy immediately with an oral thiazide or organomercurial preparation in *moderate* dosage and continuing with a reduced *maintenance dose* Any one of the preparations discussed can be *given safely* and successfully.

restricted salt intake and excessive sodium loss from vigorous diuretic therapy or vomiting. Except in the latter situations, administration of salt solutions is dangerous. Preferably one should discontinue the thiazide drug, restrict fluid intake moderately, and treat with intermittent doses of a mercurial diuretic primed with ammonium chloride or other chloride salt and aminophylline. This may restore a more normal serum sodium level.

2. *Hypochloremic Alkalosis* This metabolic disturbance is also a manifestation of long-standing heart failure, aggravated by protracted diuretic therapy with chloride-depleting agents It is an indication to temporarily discontinue thiazide therapy and to carry out the corrective measure for this condition outlined in the section on mercurial diuretics. These measures are essential to restore responsiveness to further diuretic therapy.

3. *Hypopotassemia* This electrolyte disturbance has become of increasing importance with the ever-increasing use of the potent thiazide agents, which may cause relatively greater potassium excretion than other diuretics. The degree of potassium depletion is related also to the severity of the heart failure, being aggravated by excess aldosterone secretion and reduced sodium excretion. Serum potassium levels should be checked in all patients on prolonged therapy. The potassium depletion is less marked with the newer thiadiazine analogues than with chlorothiazide. Despite this, it is desirable to supplement the diuretic therapy with moderate doses of potassium salts, such as potassium chloride (1 to 2 Gm daily) or potassium triplex (5 ml t.i.d.) In fact, most of the commercial preparations are now available in a combined tablet with 500 mg potassium chloride, which may be adequate for prophylactic purposes. The diet should be adjusted so as to provide a more liberal sodium and potassium intake High-potassium foods should be included, such as citrus fruits and juices, meat, bran, and milk When significant hypopotassemia already exists, larger supplemental doses of potassium salts are required and the daily dosage and frequency of administration of the diuretic agent should be reduced.

The two important dangers of severe hypopotassemia are *kidney damage* with impaired renal function and *increased myocardial irritability* The latter may precipitate or aggravate digitalis toxicity in patients on combined digitalis and thiazide therapy. *There appears to be a direct relationship between myocardial concentration of potassium and the dose of digitalis required to produce toxicity* In acute heart failure, digitalization must proceed more cautiously if the patient is simultaneously receiving large doses of a thiazide drug or other potassium-depleting agent and is excreting increased amounts of urine and electrolytes. Serious *cardiac arrhythmias* may be precipitated by potassium depletion, even before the average toxic range of the digitalis preparation is reached. Similarly, in patients on long-term maintenance therapy with both digitalis and a thiazide agent, strict attention must be paid to dosage of the drugs, dietary potassium and sodium intake, and supplemental potassium administration. In such patients, the minimum rather than the maximum effective maintenance dose of each drug is indicated. The thiazides must be discontinued and oral potassium therapy instituted whenever digitalis toxicity is suspected or there is a significant fall in serum potassium.

When frank digitalis toxicity has developed, larger oral dosage (5 to 7 Gm daily) or intravenous infusion (3 to 4 Gm) of potassium salts becomes necessary, as outlined previously (see Digitalis Toxicity). If continued diuretic therapy is indicated, it would be safer to give intermittent doses of a parenteral mercurial rather than daily doses of a thiazide agent

Spironolactones. Several years ago, it was observed clinically that the *corticosteroids,* which normally enhance tubular reabsorption of sodium and water and create edema, may exert a paradoxic effect on patients with advanced heart failure and intractable edema by increasing sodium and water excretion (Reimer). Corticosteroid therapy was noted to restore responsiveness to the mercurial and thiazide diuretics The diuretic effect of steroid therapy was attributed to increased glomerular filtration rate, inhibition of antidiuretic hormone, and an antagonistic effect on the sodium reabsorption action of aldosterone *The latter* was considered the most important mechanism

More recently a new group of *antialdosterone agents* has been introduced, viz., the spironolactones (17-spirolactosteroids). Their use is based on the observation that severe or prolonged congestive failure is associated with a state of secondary *hyperaldosteronism. The ex-*

the primary etiologic factors, are recognized early and the appropriate specific treatment given, if available.

ERRORS IN TREATMENT. One must review the previous therapeutic measures carefully in cases of resistant heart failure to determine if the patient has been undertreated or overtreated.

Undertreatment. Periodically the adequacy of rest, salt restriction, digitalization, and diuretic therapy must be reviewed carefully. If it is suspected that previous management has been inadequate, the patient should be placed at *complete bed rest* and given a carefully supervised low-salt diet (500 mg sodium initially) containing high-potassium foods (fruits and fruit juices, meats, low-sodium milk); the dosage of digitalis and diuretic agents should be increased to the maximum effective levels short of toxicity Various combinations of diuretics, as already discussed, should be tried, as different agents may have additive or potentiating effects.

Overtreatment. Congestive failure may be aggravated by deleterious myocardial and renal effects of overenthusiastic application of salt restriction, digitalization, and diuretic therapy These are common causes for digitalis toxicity and electrolyte-depletion syndromes, which may aggravate the myocardial failure, depress renal function, and produce unresponsiveness to further therapy when the patient has been overtreated with mercurials or thiazine diuretics These must be temporarily discontinued to allow restoration of normal renal function and metabolic and electrolyte balance if possible.

ELECTROLYTE DERANGEMENTS. Careful studies of the serum electrolytes have been emphasized as an essential step in the evaluation of all patients with resistant heart failure. The presence of normal serum electrolytes would suggest that one could continue to pursue a regimen of intensive diuretic therapy. On the other hand, significant lowering of the serum sodium, chloride, or potassium, elevation of blood urea nitrogen, or evidence of alkalosis, would be an indication to temporarily discontinue diuretic therapy in favor of attempts to correct the electrolyte and metabolic derangements that have led to the state of unresponsiveness. All previously described methods must be applied to correct dilutional hyponatremia, hypochloremic alkalosis, and hypopotassemia, if present. The oral or intravenous administration of acidifying and chloruretic agents to elevate serum chloride (above 100 mEq/liter) and to produce an acid urine and increased urinary chloride excretion (above 40 mEq/liter) represents a distinct advance in the correction of hypochloremic alkalosis, which probably is the most important metabolic disturbance in advanced or resistant heart failure, and the one most likely to be the cause of loss of response to mercurial therapy. Alternating or combining the chloruretic agents with potassium salts will have the additional value of correcting or preventing hypopotassemia

Observation of the patient's *response to the* digitalis and diuretic therapy (effect on dyspnea, weight, visible edema, etc.) is important for regulation of dosage and frequency of administration of digitalis and diuretic agents and *determination of degree of restriction of activity* and salt intake required.

Moderate to Severe Heart Failure. In such cases, therapy must be more vigorous. Complete bed rest, oxygen, morphine or other narcotic agents, moderate to severe restriction of salt intake to 1 Gm or less, and rapid digitalization are instituted immediately. An attempt is *made to achieve maximal therapeutic dosage* short of toxicity, with a rapidly acting oral or parenteral glycoside. In previously digitalized patients, dosage should be carefully reviewed to determine if the patient is under- or over-*digitalized, and the digitalis dose should be* adjusted accordingly A program of 3 or 4 days of active diuretic therapy should be started, giving either a mercurial injection daily or on alternate days or a potent oral thiazide preparation in maximum effective doses at 6- to 12-hr intervals. For example, chlorothiazide 1 Gm, or hydrochlorothiazide 100 mg, or benzydroflumethiazide 10 mg, can be given twice daily. If diuresis is inadequate and weight loss too slow, a parenteral mercurial is administered every third or fourth day. Additional diuretic effects can be achieved by such combined therapy When an improved cardiac state is obtained, maintenance therapy is continued with intermittent mercurial injections and a daily oral diuretic, the dosage depending on the severity of residual signs of failure During this early stage, it is wise to obtain determinations of serum electrolytes and other chemistry values, to exclude the presence of electrolyte disturbance or impaired renal function. The findings will dictate the necessity for altering the dietary and diuretic regimen and for other supplementary therapy to correct metabolic and electrolyte derangements These include particularly *hypochloremia* and *hypopotassemia*, which, if present, are responsible for diminished response to diuretic therapy, impaired renal function, and predisposition to digitalis toxicity.

If circulatory congestion and edema persist despite the above regimen, priming of the mercurial agent with acidifying or chloruretic salts is indicated to potentiate or restore diuresis. Ammonium chloride (8 mg daily), or lysine, or arginine monohydrochloride (40 Gm daily), is administered orally for 3 or 4 days, and, on the following day, the mercurial injection is given. Aminophylline (0 5 Gm) may be administered intravenously 1 to 3 hr later or by rectal infusion on the same morning. This cycle can be repeated every 4 to 5 days until a satisfactory loss of edema has been obtained. In severe chronic failure, various other combinations of diuretics can be given a trial, such as thiazides combined with an oral organomercurial, or short courses of a spironolactone combined with a mercurial or a thiazide. Also, *any sizable serous effusion in the pleural or peritoneal cavities should be drained if response to diuretic therapy is slow.*

Resistant or Refractory Heart Failure. Patients with advanced heart disease often reach *a stage when their failure becomes resistant to* the normal therapeutic measures. Such patients must be studied carefully to determine the factors responsible for their refractory state The following factors must be considered as possible causes:

ADVANCED MYOCARDIAL DISEASE Irreversible heart failure may develop in the terminal stages of long-standing myocardial and valvular diseases or in severe acute myocardial damage, as in myocardial *infarction*, *myocarditis*, etc The cardiac reserve is the primary factor which determines whether any form of therapy would be effective in restoring adequate myocardial and renal hemodynamics.

EXTRACARDIAC CIRCULATORY CONGESTION OR OVERLOADING Heart failure with edema and venous congestion associated with *inflammatory*, *circulatory*, hematologic, or metabolic states will not respond to the usual measures without specific therapy for these conditions This includes *steroids* for rheumatic or nonspecific carditis or pericarditis, postmyocardial infarction or postcommissurotomy syndrome, glomerulonephritis, nephrosis, and lupus erythematosus, *thiamine* for nutritional deficiencies or beriberi, *iron and blood replacement* in severe anemias and chronic hemorrhage, *albumin and protein replacement* in hypoproteinemia, *anticoagulants* for recurrent pulmonary emboli, *antibiotics* for myocardial or pulmonary infection or sepsis, *antithyroid drugs or surgery* for hyperthyroidism; and *thyroid* administration for hypothyroidism or myxedema Therapy for heart failure will be unsuccessful unless these conditions, which may be

the primary etiologic factors, are recognized early and the appropriate specific treatment given, if available

ERRORS IN TREATMENT. One must review the previous therapeutic measures carefully in cases of resistant heart failure to determine if the patient has been undertreated or overtreated.

Undertreatment. Periodically the adequacy of rest, salt restriction, digitalization, and diuretic therapy must be reviewed carefully. If it is suspected that previous management has been inadequate, the patient should be placed at *complete bed rest* and given a carefully supervised low-salt diet (500 mg sodium initially) containing high-potassium foods (fruits and fruit juices, meats, low-sodium milk); the dosage of digitalis and diuretic agents should be increased to the maximum effective levels short of toxicity. Various combinations of diuretics, as already discussed, should be tried, as different agents may have additive or potentiating effects.

Overtreatment. Congestive failure may be aggravated by deleterious myocardial and renal effects of overenthusiastic application of salt restriction, digitalization, and diuretic therapy. These are common causes for digitalis toxicity and electrolyte-depletion syndromes, which may aggravate the myocardial failure, depress renal function, and produce unresponsiveness to further therapy when the patient has been overtreated with mercurials or thiazine diuretics These must be temporarily discontinued to allow restoration of normal renal function and metabolic and electrolyte balance if possible.

ELECTROLYTE DERANGEMENTS. Careful studies of the serum electrolytes have been emphasized as an essential step in the evaluation of all patients with resistant heart failure. The presence of normal serum electrolytes would suggest that one could continue to pursue a regimen of intensive diuretic therapy. On the other hand, significant lowering of the serum sodium, chloride, or potassium, elevation of blood urea nitrogen, or evidence of alkalosis, would be an indication to temporarily discontinue diuretic therapy in favor of attempts to correct the electrolyte and metabolic derangements that have led to the state of unresponsiveness. All previously described methods must be applied to correct dilutional hyponatremia, hypochloremic alkalosis, and hypopotassemia, if present. The oral or intravenous administration of acidifying and chloruretic agents to elevate serum chloride (above 100 mEq/liter) and to produce an acid urine and increased urinary chloride excretion (above 40 mEq/liter) represents a distinct advance in the correction of hypochloremic alkalosis, which probably is the most important metabolic disturbance in advanced or resistant heart failure, and the one most likely to be the cause of loss of response to mercurial therapy. Alternating or combining the chloruretic agents with potassium salts will have the additional value of correcting or preventing hypopotassemia.

Observation of the patient's response to the digitalis and diuretic therapy *(effect on dyspnea, weight, visible edema, etc.)* is important for regulation of dosage and frequency of administration of digitalis and diuretic agents and determination of degree of restriction of activity and salt intake required.

Moderate to Severe Heart Failure. In such cases, therapy must be more vigorous. Complete bed rest, oxygen, morphine or other narcotic agents, moderate to severe restriction of *salt intake to 1 Gm or less, and rapid digitalization* are instituted immediately. An attempt is made to achieve maximal therapeutic dosage short of toxicity, with a rapidly acting oral or parenteral glycoside In previously digitalized patients, dosage should be carefully reviewed to determine if the patient is under- or overdigitalized, and the digitalis dose should be adjusted accordingly. A program of 3 or 4 days of active diuretic therapy should be started, *giving either a mercurial injection daily or on* alternate days or a potent oral thiazide preparation in maximum effective doses at 6- to 12-hr intervals For example, chlorothiazide 1 Gm, or hydrochlorothiazide 100 mg, or benzydroflumethiazide 10 mg, can be given twice daily. If diuresis is inadequate and weight loss too slow, a parenteral mercurial is administered every third or fourth day Additional diuretic effects can be achieved by such combined therapy. When an improved cardiac state is obtained, maintenance therapy is continued with intermittent mercurial injections and a daily oral diuretic, the dosage depending on the severity of residual signs of failure During this early stage, it is wise to obtain determinations of serum electrolytes and other chemistry values, to exclude the presence of electrolyte disturbance or impaired renal function The findings will dictate the necessity for altering the dietary and diuretic regimen and for other supplementary therapy to correct metabolic and electrolyte derangements These include particularly *hypochloremia* and *hypopotassemia, which, if present, are responsible for diminished response to diuretic therapy*, impaired renal function, and predisposition to digitalis toxicity.

If circulatory congestion and edema persist despite the above regimen, priming of the mercurial agent with acidifying or chloruretic salts is indicated to potentiate or restore diuresis. Ammonium chloride (8 mg daily), or lysine, or arginine monohydrochloride (40 Gm *daily), is administered orally for 3 or 4 days*, and, on the following day, the mercurial injection is given. Aminophylline (0 5 Gm) may be administered intravenously 1 to 3 hr later or by rectal infusion on the same morning. This cycle can be repeated every 4 to 5 days until a satisfactory loss of edema has been obtained. In severe chronic failure, various other combinations of diuretics can be given a trial, such as thiazides combined with an oral organomer*curial, or short courses of a spironolactone com*bined with a mercurial or a thiazide Also, *any sizable serous effusion in the pleural or peritoneal cavities should be drained if response to diuretic therapy is slow.*

Resistant or Refractory Heart Failure. Patients with advanced heart disease often reach a stage when their failure becomes resistant to the normal therapeutic measures Such patients must be studied carefully to determine the fac*tors responsible* for their refractory state. The following factors must be considered as possible causes:

ADVANCED MYOCARDIAL DISEASE. Irreversible heart failure may develop in the terminal stages of long-standing myocardial and valvular diseases or in severe acute myocardial damage, as in myocardial infarction, myocarditis, etc The cardiac reserve is the primary factor which determines whether any form of therapy would be effective in restoring adequate myocardial and renal hemodynamics

EXTRACARDIAC CIRCULATORY CONGESTION OR OVERLOADING. Heart failure with edema and venous congestion associated *with* inflammatory, circulatory, hematologic, or metabolic states will not respond to the usual measures *without specific* therapy for these conditions. This includes *steroids* for rheumatic or nonspecific carditis or pericarditis, postmyocardial infarction or postcommissurotomy syndrome, glomerulonephritis, nephrosis, and lupus erythematosus, *thiamine* for nutritional deficiencies or beriberi; *iron and blood replacement* in severe anemias and chronic hemorrhage, *albumin and protein replacement* in hypoproteinemia, *anticoagulants* for recurrent pulmonary emboli, *antibiotics* for myocardial or pulmonary infection or sepsis; *antithyroid drugs or surgery* for hyperthyroidism, and *thyroid* administration for hypothyroidism or myxedema. Therapy for heart failure will be unsuccessful unless these conditions, which may be

Electrokymography and other graphic tracings in coronary heart disease

ALDO A. LUISADA AND ALDO JACONO

PHONOCARDIOGRAM

The most typical change observed after a myocardial infarct is the disappearance of the rapid vibrations of the 1st sound. This sound then presents a *prolonged series of slow vibrations* which are *frequently small but may* be of normal height. After the acute stage, it is possible to observe large extra sounds in diastole (*triple rhythm, quadruple rhythm*). These additional sounds are heard only if they are very loud, on account of their low pitch (Fig. 10-20 and 10-23B).

LOW-FREQUENCY TRACINGS OF THE PRECORDIUM

Cardiographic tracings are obtained with difficulty in the acute stage of myocardial infarction because of weak cardiac action. When a good tracing is obtained, a slow development of all waves is usually observed (Fig. *10-20*). This is due to the existence of an area of soft tissue in the left ventricle. By absorbing part of the energy of contraction, this area prevents a rapid rise of pressure and may even cause a less rapid closure of the mitral valve. Therefore, while the 1st sound becomes al-

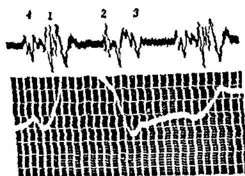

Fig. 10-20. Phonocardiogram (stethoscopic) and low-frequency tracing at apex in a case of coronary heart disease and history of an infarct. Quadruple rhythm. Slow diastolic waves. Slow motion of apex.

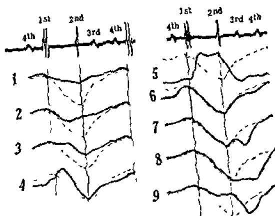

Fig. 10-21. Scheme of the abnormalities of the ventricular EKy (continuous line) compared with the normal tracing (dotted line). 1. Decreased amplitude of contraction. 2. Early end of contraction. 3. Late onset of contraction. 4. Early systolic distention followed by normal contraction. 5. Systolic distention (dynamic aneurysm). 6. Marked presystolic distention. 7. Deep early diastolic rebound. 8. Late systolic distention. 9. Decreased amplitude of contraction and deep early diastolic drop. (From Luisada and Fleischner. Acta. Cardiol. 1948.)

In human beings, the conditions of examination after a myocardial infarction are unfavorable. However, Sampson and Dack described the rapid appearance of dynamic alterations. At the beginning, as a rule, there is a paradoxic expansion; later, during the evolution of the lesions, one or the other of the previous types of changes is observed. Therefore, the functional disorders revealed by roentgen kymography are logically connected with the sequence of structural changes.

The different modifications of left ventricular dynamics represent a wide range, from the simplest (reduction of amplitude) to the more severe (paradoxic systolic expansion). These alterations are usually observed at the apex, but they spread more or less toward the base according to the severity of the case. When two or more types of dynamic changes are observed, the *most severe are always at the apex* In certain cases, the entire left ventricular border is immobile, corresponding to widespread and severe myocardial damage. The oblique positions show the horizontal extension of the dynamic alterations. They are more evident in the RAO position and decrease progressively in severity when the rotation is changed to the LAO position.

In patients with coronary disease, alterations of left ventricular dynamics are observed with great frequency. the author recorded them in 91 per cent of cases (141 times in 155 subjects examined) They are localized in 125 cases (80 per cent) and extended to the entire left ventricular border in 16 cases (10 per cent)

The frequency of the various types of changes is as follows· undulation and reduction, 48 per cent, tremulation, 50 per cent; complete immobility, 56 per cent, paracardiac blurring, 50 per cent; delayed contraction and paradoxic pulsation, more rarely These values are in accord with the findings of Master, Dack, Susmann, and Prinzmetal They are found both in anterior and posterior myocardial infarction The ischemic or infarcted areas localized by electrocardiography do not correspond exactly to the localization of anomalies of left ventricular dynamics because the latter are most often at the apex. This was confirmed by Heim de Balsac and Alessandris in a series of 71 cases of posterior infarction Increased severity of disorders is revealed by the fact that a complete immobility substitutes undulation or reduction of pulsations, on the other hand, even in case of improvement, the paradoxic pulsation is usually irreversible.

The evolution of left ventricular dynamic changes is not strictly connected with that of the electric changes. The amplitude of the contractions may decrease before any other clinical signs; it may follow an evolution parallel to that of ECG changes; or it may evolve in a complete opposite manner. normal dynamics is then found with still abnormal ECG or, on the contrary, persistence of an altered dynamics when the ECG has returned to normal. In the same way, the alterations of ventricular dynamics in patients with coronary disease are not directly related to other signs of altered myocardial function, such as triple rhythm (gallop rhythm) or dilatation of the heart. The roentgen kymographic study of cardiac dynamics supplies important data in coronary diseases, which help, not only for diagnosis, but in order to follow the evolution of the disease Therefore, the author considers left ventricular roentgen kymography as a routine test to be done in all patients with coronary disease. The variations observed are neither surprising or illogical: cardiac dynamics, vibrations revealed by auscultation, changes of intracardiac pressures, and changes of the electric forces are different phenomena, all related to the ventricular activity but not necessarily connected. Therefore, their modifications may be discordants

The study of cardiac dynamics opens the way to new concepts. The observation of larger contractions over the posterior contour of the left ventricle leads to the belief that the left ventricular contraction is not concentric, but has a greater amplitude in a PA plane than in a lateral. The fact that the left ventricle continues to propel blood when all its left border is immobile leads to the belief that, in such cases, the posteroinferior wall and the septum perform all the necessary work. The frequency of the dynamic changes observed at the apex, even in cases of posterior infarction, is more difficult to explain; Master and Dack suggested that it is due to the spiral arrangement of the myocardial bundles inserted on the valvular rings

either the apex or the lateral wall; in 1 case (incompletely studied), a *posterolateral abnormality was found*, in 1, no abnormality. In 7 cases, there was a history of repeated episodes of infarction or of attacks of severe, prolonged precordial pain. In all of them, *marked abnormalities of contraction* were found in the anterior, posterior, and lateral walls The only remaining case had an ECG indicating left ventricular strain, while a large area of the lateral wall of the left ventricle presented abnormalities of contraction These coincidences amount to nearly a 90 per cent identity in the topography of the lesion between the ECG and EKy

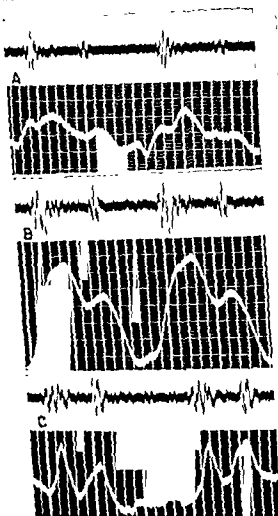

Fig. 10-24 Abnormal pulsations of lateral border in case of posterolateral infarct A EKy of apex, minimal systolic distention. B. EKy above apex severe systolic distention (paradoxical pulsation). C. EKy at upper left border: double pulsation.

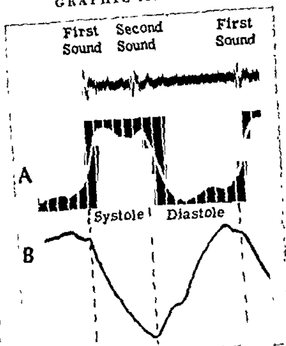

Fig. 10-25. *Old anterolateral infarct with dynamic aneurysm. A Paradoxical, plateau-like expansion in systole. B Scheme of normal pulsation, for comparison (From Luisada, Med. Clin. No. America 1952)*

Some of the abnormalities can be found in other conditions than *myocardial infarction*. For example, a marked *diastolic rebound* was found in acquired valvular lesions and in ventricular septal defects; initial distention followed by contraction was found in certain cases with aortic insufficiency or arterial hypertension Presystolic distention may be found in cases with an atrial type of triple rhythm Therefore, these abnormalities have *no* diagnostic significance in regard to myocardial infarction Some of the diastolic abnormalities are related *directly* to abnormalities of systole and represent a necessary *consequence* of the latter Whenever an inverted movement in early diastole follows an inverted systolic pulsation, it is apparent that it is connected with it and does not deserve *special* mention On the other hand, an inverted diastolic wave can be found as an isolated phenomenon, and then it represents a well-defined and noteworthy abnormality

A *rebound in early diastole represents* a typical abnormality whenever it is *marked* and constitutes a *seemingly* new wave in that phase. The opposite phenomenon is repre-

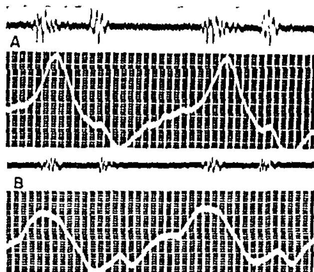

Fig. 10-22. Electrokymogram in a case of antero-lateral infarct. A. Early systolic distention followed by normal contraction at apex. B. Normal dynamics above apex.

tered, all the low-frequency vibrations of the chest also become slow (Fig 10-20).

ELECTROKYMOGRAM

Electrokymography permits an accurate study of the movements of the left ventricular walls and gives tracings which may have diagnostic value.

Various abnormalities have been observed (Luisada and Fleischner; Dack et al, 1950, *Samet et al*) (*Fig 10-21*) Some of them have been found typical of a circumscribed damage to the ventricular wall; others, on the other hand, are not specific and may also be observed in cases with diffuse myocardial damage.

Several abnormal patterns were observed *during systole* Four of them can be grouped together, being an expression of the same phenomenon, i e, a decreased amplitude of the ventricular wave of contraction (Fig. 10-22): reduced amplitude, early end, late onset, or absence of the wave

Two other systolic patterns reveal a more advanced disturbance because they indicate a tendency toward distention (Fig 10-23 to 10-26)· (1) *early distention* followed by a normal ventricular wave, (2) *inverted pulsation* (so-called *paradoxical pulsation*).

In addition to these, a bizarre phenomenon consisting of an M-shaped complex during systole was occasionally observed Various abnormal patterns can also be observed during diastole: (1) marked rebound in early diastole (systolic-diastolic M) (Fig. 10-21); (2) absence of rapid rise in early diastole, (3) drop of the tracing in early diastole, (4) marked distention during presystole

CORRELATION OF ELECTROCARDIOGRAPHIC AND ELECTROKYMOGRAPHIC FINDINGS

Out of 20 cases studied by the authors, 7 were instances of relatively recent myocardial infarction (patients studied within 3 to 6 weeks from the onset of the attack), 8 were instances of old infarctions which had taken place from one to several years previously. The other 5 cases had had repeated infarctions but were also observed within 3 to 6 weeks after a new episode. In 4 cases, the ECG indicated *posterior myocardial infarction;* in all of them, the abnormality of contraction was located in the posterior wall and extended to the lateral wall.

In 8 cases, the ECG indicated *anterior or anterolateral myocardial infarction.* In 6 of them, the abnormality of contraction was located in the anterior wall and extended to

Fig. 10-23. Electrokymogram in a case of antero-lateral infarct. A. "Paradoxical pulsation" (or plateau-like distention) in systole at apex. B. No contraction above apex.

2. *Inverted pulsation (paradoxical pulsation) of a circumscribed area of the ventricular myocardium.* In typical cases, this inverted pulsation assumes the aspect of a *plateau*, indicating that the inert wall is passively distended by intraventricular pressure. This type of pulsation may be associated with the existence of a well-defined bulge of the ventricular silhouette on chest films. In such cases, the name of *ventricular aneurysm* should be used. In other cases, bulging occurs only in systole while no bulge is present in diastole. This phenomenon, occasionally observed on fluoroscopy, is hardly noticeable on roentgenograms, these, even if taken at the maximum of systole, would show but a minute projection, hardly detectable without simultaneous observation of the two opposite motions

It should be kept in mind that the dynamic significance of such an inverted pulsation is similar to that of an aneurysm The wall distends in systole, absorbing part of the dynamic effort of the normal myocardium; it collapses in diastole, disturbing the normal filling and spilling its retained blood into the rest of the ventricular cavity. This similarity, already emphasized by Murray (1947), justifies the term of "dynamic aneurysm" in instances where a typical inverted pulsation is found without any persisting bulge in the profile of the left ventricle It is likely, though not yet demonstrated, that a dynamic aneurysm corresponds to the formation of a "niche" in the ventricular wall, i e, to a remarkable thinning of the wall This fact, which pathologists still call "aneurysm," may not correspond to an aneurysm in a chest film Thus, the EKy is more accurate in its recognition of a severe lesion of the wall than the chest film

Both these typical phenomena, the lack of pulsation and the inverted (or paradoxical) pulsation, were encountered either on the anterior or posterior wall, respectively, or in one of these locations but also extending to the lateral wall, or in a large area including anterior, lateral, and posterior walls The most common occurrence is that of either an anterior or a posterior location with extension to the lateral wall.

Here a remark on terminology may be in order The roentgenologic and electrocardiographic terminologies are not necessarily in perfect harmony. The "anterior wall" of the electrocardiologist is actually "anterolateral." The roentgenologist, on the other hand, calls lateral wall the area adjacent to the profile of the heart silhouette as observed with the patient in the PA position. This profile changes its topographic relation with changes of the position of the heart, such as rotation. From this, it seems quite likely that roentgenologic and electrocardiographic terms overlap each other occasionally and may require reconciliation. As to the extent of the myocardial damage, no strict identity should be expected in electrokymographic and electrocardiographic readings. The deficit in visible muscular activity is not necessarily identical in extent with, and is often larger than, the area of electrical changes.

The above observations reveal functional pulsatory disturbances, and not necessarily irreparable anatomic damage. Repeated observations over a long period of time may reveal return to normal pulsatory function in some instances, while in others, local paralysis or paradoxic pulsations will be persistently observed, indicating irreversible structural damage, probably fibrosis.

The areas of myocardium surrounding the site of occasional damage, as revealed by absent or inverted pulsation, frequently exhibit minor abnormalities They may be due to either functional disturbances at the periphery of the lesion or mechanical repercussion. It is apparent that irregular traction and shaking may occur in the border-line zone between severely damaged and normally functioning myocardium

In general, the findings of electrokymography confirm those of roentgen kymography. However, the electrokymographic method, because of the distinctness and wealth of detail as to timing and configuration of the recorded waves, and the easy approach to the anterior and posterior walls of the left ventricle, permits a better and more accurate evaluation of the various abnormalities.

It is known that, many months after an attack of myocardial infarction, the ECG may revert to normal or may present minor changes, not typical of infarction. Again, it is known that, whenever repeated infarctions take place involving the anterior and posterior walls, the alterations of the T wave indicating the position of the ventricle in which the infarction occurred are often those of the most recent lesion On the other hand, roentgen kymog-

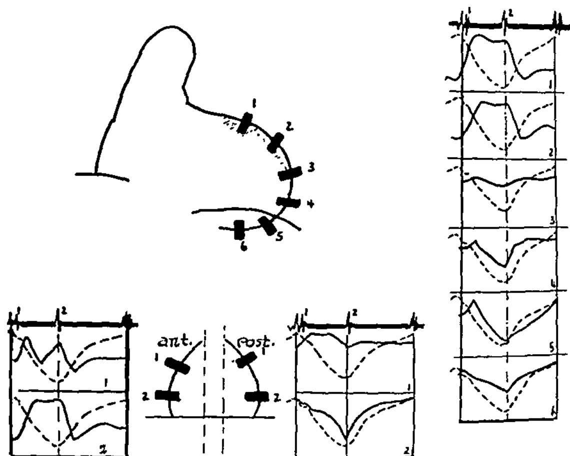

Fig. 10-26. Location of the slit and reconstruction of dynamic changes in a case with multiple infarctions. (From Luisada and Fleischner Acta Card. 1948.)

sented by the *lack of a diastolic return of the tracing toward the base line* This may or may not be connected with abnormalities of the systolic wave. When isolated, this phenomenon is worthy of note and is significant It should be kept in mind, moreover, that some of these deviations from the normal tracing, and particularly those extending over a large portion of the left ventricular contour, are apt to be due to *positional changes* of the heart.

Two abnormalities of ventricular systole, the *late onset* and the *early end of the ventricular wave*, were encountered in cases of infarction but in no other cases, so far. Nevertheless, they should not be considered as having a diagnostic value unless positional changes can be ruled out.

Two abnormalities of the systolic wave have been considered diagnostic of localized myocardial damage, in the majority of instances this being identical with myocardial infarction: [1]

1. *Reduced amplitude of the ventricular wave or disappearance of this wave in a circumscribed region of the left ventricle.*[2] Whenever the surrounding areas present large waves, this sign is definitely related to infarction As that area is functionally (and usually also anatomically) excluded from participating in active contraction, the authors have suggested the name of *local paralysis* for the phenomenon thus revealed by electrokymography

[1] This rule, while undoubtedly true in the great majority of cases, may have its exceptions Myocarditis usually causes *diffuse changes* However, the authors have observed two cases of rheumatic heart disease with valvular lesions in which a localized "paradoxical" pulsation was recorded. In one of them, subsequent autopsy revealed a large patch of fibrosis in the anterolateral wall of the left ventricle caused by old, healed rheumatic myocarditis.

[2] Landowne has remarked that the pattern of "local paralysis" indicates that the damaged area fails to move inward like the rest of the ventricular wall. Thus, it is equivalent to a moderate relative expansion. If this explanation is accepted, "local paralysis" would be equivalent to an initial "dynamic aneurysm."

2. *Inverted pulsation (paradoxical pulsation) of a circumscribed area of the ventricular myocardium.* In typical cases, this inverted pulsation assumes the aspect of a *plateau*, indicating that the inert wall is passively distended by intraventricular pressure. This type of pulsation may be associated with the existence of a well-defined bulge of the ventricular silhouette on chest films. In such cases, the name of *ventricular aneurysm* should be used. In other cases, bulging occurs only in systole while no bulge is present in diastole. This phenomenon, occasionally observed on fluoroscopy, is hardly noticeable on roentgenograms; these, even if taken at the maximum of systole, would show but a minute projection, hardly detectable without simultaneous observation of the two opposite motions.

It should be kept in mind that the dynamic significance of such an inverted pulsation is similar to that of an aneurysm. The wall distends in systole, absorbing part of the dynamic effort of the normal myocardium; it collapses in diastole, disturbing the normal filling and spilling its retained blood into the rest of the ventricular cavity. This similarity, already emphasized by Murray (1947), justifies the term of "dynamic aneurysm" in instances where a typical inverted pulsation is found without any persisting bulge in the profile of the left ventricle. It is likely, though not yet demonstrated, that a dynamic aneurysm corresponds to the formation of a "niche" in the ventricular wall, i.e., to a remarkable thinning of the wall. This fact, which pathologists still call "aneurysm," may not correspond to an aneurysm in a chest film. Thus, the EKy is more accurate in its recognition of a severe lesion of the wall than the chest film.

Both these typical phenomena, the lack of pulsation and the inverted (or paradoxical) pulsation, were encountered either on the anterior or posterior wall, respectively, or in one of these locations but also extending to the lateral wall, or in a large area including anterior, lateral, and posterior walls. The most common occurrence is that of either an anterior or a posterior location with extension to the lateral wall.

Here a remark on terminology may be in order. The roentgenologic and electrocardiographic terminologies are not necessarily in perfect harmony. The "anterior wall" of the electrocardiologist is actually "anterolateral." The roentgenologist, on the other hand, calls lateral wall the area adjacent to the *profile of the heart silhouette* as observed with the patient in the PA position. This profile changes its topographic relation with changes of the position of the heart, such as rotation. From this, it seems quite likely that roentgenologic and electrocardiographic *terms* overlap each other occasionally and may require reconciliation. As to the extent of the myocardial damage, no strict *identity* should be expected in electrokymographic and electrocardiographic readings. The deficit *in visible* muscular activity is not necessarily *identical in* extent with, and is often larger than, *the area of* electrical changes.

The above observations reveal functional pulsatory disturbances, and not necessarily irreparable anatomic damage. Repeated observations over a long period of time may reveal return to normal pulsatory function *in some* instances, while in others, local paralysis or paradoxic pulsations will be persistently observed, indicating irreversible structural damage, probably fibrosis.

Cardiopexy

SAMUEL A. THOMPSON

Value of Surgery. In myocardial ischemias. and especially in coronary disease, some patients sustain severe myocardial damage and are incapacitated beyond the stage of satisfactory recovery. *Surgery may offer these patients a chance for further rehabilitation which cannot be secured by nonsurgical methods.* During the course of coronary disease, a change from ischemia to hyperemia of the myocardium can give some protection from further serious damage by the ischemic process. *Thus the value of surgery in coronary disease is chiefly that of rehabilitation and protection.*

Principles of Surgery. There are two general principles in the surgical treatment of coronary disease. One is *palliative* and consists in interrupting the nerve pathways through which the painful impulses are carried. The other is *definitive* and consists in the development of an additional blood flow and distribution to the myocardium known as revascularization.

METHODS OF REVASCULARIZATION

Two equally important factors must be considered in correcting myocardial ischemia: they are an *increased* volume of blood and a satisfactory distribution of this blood through the myocardium. Failure to establish either of these will result in failure to correct the ischemia.

The gradual narrowing and final occlusion in coronary artery disease occurs *principally* in the main arteries rather than in the secondary branches, and either the right or left side may be primarily involved. Correcting an insufficient myocardial blood supply and distribution should be aimed at the entire myocardium *and not* at the right or left ventricle. Much of the present-day surgery for the relief of coronary disease is directed toward increasing the blood volume delivered to only one section of the myocardium, namely, the left ventricle, and yet the right ventricle may be the site of the greatest pathologic changes.

Overcoming an inadequate blood distribution because of a blocked coronary system must be done through the growth of new blood vessels or new anastomoses between already existing vessels, such as the communication of extracardiac vesels with the coronary system, distal to the obstruction, and stimulating an increase in the inter- and intracoronary anastomoses.

Sources of Collateral Supply. The source of the additional blood flow may be extracardiac, intracardiac, or a combination of both. The extracardiac source may be from vascular or tissue grafts or from the development of the *residual myocardial circulation.* The term residual myocardial circulation indicates those small blood vessels which actually constitute a preformed source of collateral circulation (Hudson et al.). They have their origin around the base of the heart and great vessels and from the pericardium. When the coronaries become blocked, *they are the principal remaining sources of blood supply.* This circulation is capable of tremendous growth and expansion under proper stimulation, and one of the strongest stimulants is local or surface irritation of the pericardium and myocardium.

A method of increasing the residual myocardial circulation through the pericardium is the *bilateral ligation of the internal mammary*

raphy demonstrated clearly the results of both the recent and old lesions (Gubner and Crawford, 1939; Dack et al., 1940). The authors had the same experience with electrokymography. They had the general impression that the myocardial lesions, revealed by the EKy, were more extensive than those indicated by electrocardiography, since the lateral wall appeared to be involved frequently even in cases of frank "anterior" or "posterior" infarction

While a "dynamic aneurysm" is typical of the scarring of an old infarct, experimental studies (Tennant and Wiggers) and roentgen kymographic observations (Dack et al) indicate the likelihood that a recent infarct also presents this phenomenon.

Cardiopexy

SAMUEL A. THOMPSON

Value of Surgery. In myocardial ischemias, and especially in coronary disease, some patients sustain severe myocardial damage and are incapacitated beyond the stage of satisfactory recovery. Surgery may offer these patients a chance for further rehabilitation which cannot be secured by nonsurgical methods. During the course of coronary disease, a change from ischemia to hyperemia of the myocardium can give some protection from further serious damage by the ischemic process. Thus the value of surgery in coronary disease is chiefly that of rehabilitation and protection.

Principles of Surgery. There are two general principles in the surgical treatment of coronary disease. One is *palliative* and consists in interrupting the nerve pathways through which the painful impulses are carried. The other is *definitive* and consists in the development of an additional blood flow and distribution to the myocardium, known as revascularization.

METHODS OF REVASCULARIZATION

Two equally important factors must be considered in correcting myocardial ischemia: they are an increased volume of blood and a satisfactory distribution of this blood through the myocardium. Failure to establish either of these will result in failure to correct the ischemia.

The gradual narrowing and final occlusion in coronary artery disease occurs principally in the main arteries rather than in the secondary branches, and either the right or left side may be primarily involved. Correcting an insufficient myocardial blood supply and distribution should be aimed at the entire myocardium and not at the right or left ventricle. Much of the present-day surgery for the relief of coronary disease is directed toward increasing the blood volume delivered to only one section of the myocardium, namely, the left ventricle, and yet the right ventricle may be the site of the greatest pathologic changes.

Overcoming an inadequate blood distribution because of a blocked coronary system must be done through the growth of new blood vessels or new anastomoses between already existing vessels, such as the communication of extracardiac vesels with the coronary system, distal to the obstruction, and stimulating an increase in the inter- and intracoronary anastomoses.

Sources of Collateral Supply. The source of the additional blood flow may be extracardiac, intracardiac, or a combination of both. The *extracardiac source* may be from vascular or tissue grafts or *from the development of the residual myocardial circulation.* The term residual myocardial circulation indicates those small blood vessels which actually constitute a preformed source of collateral circulation (Hudson et al.). They have their origin around the base of the heart and great vessels and from the pericardium. When the coronaries become blocked, they are the principal remaining sources of blood supply. This circulation is capable of tremendous growth and expansion under proper stimulation, and one of the strongest stimulants is local or surface irritation of the pericardium and myocardium.

A method of increasing the residual myocardial circulation through the pericardium is the bilateral ...

arteries just below the pericardiophrenic branches (Battezzati et al.). This produces an increased vascularization of the pericardium. The full benefit of this increased vascularization cannot be utilized unless there is an intimate connection of the pericardium to the myocardium with communication of the pericardial and myocardial vessels below and distal to the coronary obstruction.

USE OF GRAFTS

Many tissues have been used as grafts, but the one tissue which has been most successfully used for a long period of time is the pericardium (Thompson, 1940). The blood supply of the pericardium is abundant and is especially suited because of its proximity. The formation of a granulomatous graft or an area of granulomatous tissue between the graft and host is a valuable addition, provided that this granulomatous area is permanent. In addition to being composed principally of blood vessels, the granulomatous area acts as a bridge through which the extracardiac and intracardiac blood vessels can communicate and through which the vascular continuity can be reestablished proximal and distal to an occlusion.

At the present time the principal vascular graft used is the *internal mammary artery* This operation was devised by *Vineberg*, who has used it successfully for a number of years.[1] However, the greatest increase in the intracardiac blood flow comes through the development of intercoronary and intracoronary anastomoses, giving a more extensive and adequate distribution of the blood This is best accomplished by *surface or local irritation of the myocardium* The importance of irritation is great for irritation produces inflammation and inflammation results in *hyperemia*, which is the reverse of myocardial ischemia Prolonged irritation is better than temporary, and if the irritation is permanent, the best results may be expected.

Another method of myocardial revascularization which utilizes both increased blood supply and distribution is *cardiopericardiopexy* (cardiopexy, for short) This is essentially a form of *permanent surface irritation* and is accomplished by distributing an irritant powder over the surface of the epicardium. This irritant powder (magnesium silicate–U.S.P. talc) is not absorbed by the lymphatics or removed by the phagocytes and results in an area of granulomatous tissue, adherent on its outer side to the pericardium and on its inner side to the myocardium. This granulomatous adhesive area acts as a vascular bridge for the communication of blood vessels of the pericardium and mediastinal structures with those of the coronary system. The irritant also improves the intracardiac blood distribution by stimulating an increase in the number of new vessels to the myocardium beyond the site of the occlusion, as well as an increase in the intercoronary and intracoronary anastomoses. The granulomatous area never changes to scar tissue nor becomes avascular, because the irritant is never removed and it thus acts as a permanent source of collateral circulation The author has been able to demonstrate the permanency of the blood vessels in the granulomatous area as well as the continued presence of the irritant powder crystals by autopsy on patients who have died as long as 10 years after cardiopexy. The technique of cardiopexy has been described in detail (Thompson et al., 1954) and the following is a summary.

The approach to the heart is over the fifth left costal cartilage, which is removed. This approach is used because the pericardium is exposed without entering the pleural cavity. After a small opening is made in the pericardium, all fluid is aspirated to prevent the powdered talc from being washed to the dependent recesses of the pericardium The irritant powder is then widely distributed over the anterior surface and borders of the myocardium No attempt is made to cover the posterior surface as some of the powder is carried there by the beating action of the heart The pericardial opening is loosely closed, and the chest wall structures are closed in anatomic layers without drainage.

This procedure is simple, has a low mortality, and can be used in severely handicapped patients. The addition of bilateral ligation of the internal mammary arteries may further increase the good results of cardiopexy.

Another method of myocardial revascularization is the one used by Beck since 1950 This is *a combination of surface irritation plus a partial occlusion of the coronary sinus* The surface irritation is produced by mechanically scarifying the lining epicardium of the pericardium and myocardium. This is followed by

[1] See Chap. 9. *Editor.*

the application of asbestos fibers scattered over the raw areas. The partial occlusion of the coronary sinus is done by an encircling ligature tied down over a 3-mm probe Beck and Brofman (1956) report very satisfactory results with this method.

BENEFITS

The benefits from cardiopexy are rehabilitation, protection, and increase in life span. Rehabilitation comes through relief of pain and improvement in the exercise tolerance. There is protection from fear of the agonizing precordial pain coming on at unpredictable times of the day or night. There is also some protection from the fear of possible sudden death, as less than 1 per cent of cardiopexy patients (who survived the operation for as long as 3 months) have died suddenly The percentage of sudden deaths in the unoperated cases of coronary disease is much higher A study of the patients who have died subsequent to a cardiopexy and a comparison with groups of unoperated patients with coronary disease who have died leads us to believe that the life span of the operated patients averaged more than 5½ years longer than the unoperated patients

TESTS OF REVASCULARIZATION

Evidence of revascularization can be seen by the following five tests

TESTS FOR MYOCARDIAL REVASCULARIZATION

1 *Intercoronary—peripheral coronary backflow* following a central occlusion
2 Extracardiac—retrograde aortic filling of coronary arteries
3 Continued myocardial contraction in the zone of an occluded coronary artery
4 Failure of myocardial contraction when the collateral flow is removed
5 Tests of clinical improvement

The peripheral coronary backflow represents the basal intercoronary anastomosis Retrograde aortic filling of the coronaries by this maneuver is definite evidence of extracardiac anastomosis Myocardial contractions cease when the blood flow is cut off The clinical tests include relief of precordial pain, increase in exercise tolerance, performance of daily duties, and a return to some gainful occupation

The first is a test of *intracardiac collateral blood flow* as measured by the peripheral coronary backflow in both quantity and oxygen content following a central occlusion In the normal animal, the volume is about 1.7 *ml/min* Following cardiopexy, this volume is increased *to* 5 3 *ml/min* Bakst).

The second test is for *extracardiac collaterals* and is done by placing a clamp over the ascending aorta just above the origin of the coronaries, a second clamp is placed just above the diaphragm. This isolated section *of aorta is* then injected with a colored opaque solution of plastic material. In the normal animal, the coronaries are not filled by this maneuver. Following cardiopexy, this test shows filling of the coronaries in 50 per cent of the animals and is definite evidence of extracardiac anastomoses (Bakst).

The third test is *continuation of myocardial contractions in the zone supplied by an occluded coronary artery*. In normal animals, following complete occlusion of the anterior descending coronary artery, there was about a 50 per cent mortality from ventricular fibrillation or infarction. When the same occlusion *is done 2 weeks after cardiopexy*, the mortality is zero (Gregg and Dewald).

Failure of myocardial contraction when the source of the collateral flow is removed is the fourth test. In a group of animals who had a preliminary cardiopexy, a series of operations was performed in which both coronaries were ligated up to their origins Then, as a last procedure, the adherent pericardium, through which the collateral flow came, was removed, and none of the animals survived.

Clinical improvement of the patient is the fifth test While this test may be considered subjective *by some, it is certainly the most important in so* far as the patients are concerned This is measured by the relief in pain, the improvement in physical exercise tolerance, the ability to perform daily duties, and the return to a gainful occupation.

These five tests appear to give conclusive evidence of myocardial revascularization Any patient with coronary disease, with or without *a previous infarction*, who remains physically incapacitated as much as 50 per cent because of pain or dyspnea, should be considered as a candidate for surgery. The two principal contraindications are an acute or unhealed infarction and intractable congestive failure.

RESULTS

Cardiopexy was devised and first performed by the author in 1938, and that first patient is still living Since that time, the author has operated upon and observed over 400 patients. The following data shows the results: there is an operative and hospital mortality of approximately 5 per cent Using the clinical tests described above, 10 per cent of the patients have

arteries just below the pericardiophrenic branches (Battezzati et al.). This produces an increased vascularization of the pericardium. The full benefit of this increased vascularization cannot be utilized unless there is an intimate connection of the pericardium to the myocardium with communication of the pericardial and myocardial vessels below and distal to the coronary obstruction.

USE OF GRAFTS

Many tissues have been used as grafts, but the one tissue which has been most successfully used for a long period of time is the pericardium (Thompson, 1940). The blood supply of the pericardium is abundant and is especially suited because of its proximity. The formation of a granulomatous graft or an area of granulomatous tissue between the graft and host is a valuable addition, provided that this granulomatous area is permanent. In addition to being composed principally of blood vessels, the granulomatous area acts as a bridge through which the extracardiac and intracardiac blood vessels can communicate and through which the vascular continuity can be reestablished proximal and distal to an occlusion.

At the present time the principal vascular graft used is the *internal mammary artery* This operation was devised by *Vineberg*, who has used it successfully for a number of years.[1] However, the greatest increase in the intracardiac blood flow comes through the development of intercoronary and intracoronary anastomoses, giving a more extensive and adequate distribution of the blood This is best accomplished by *surface or local irritation of the myocardium* The importance of irritation is great for irritation produces inflammation and inflammation results in *hyperemia*, which is the reverse of myocardial ischemia Prolonged irritation is better than temporary, and if the irritation is permanent, the best results may be expected

Another method of myocardial revascularization which utilizes both increased blood supply and distribution is *cardiopericardiopexy* (cardiopexy, for short). This is essentially a form of *permanent surface irritation* and is accomplished by distributing an irritant powder over the surface of the epicardium This irritant powder (magnesium silicate–U.S.P. talc) is not absorbed by the lymphatics or removed by the phagocytes and results in an area of granulomatous tissue, adherent on its outer side to the pericardium and on its inner side to the myocardium. This granulomatous adhesive area acts as a vascular bridge for the communication of blood vessels of the pericardium and mediastinal structures with those of the coronary system. The irritant also improves the intracardiac blood distribution by stimulating an increase in the number of new vessels to the myocardium beyond the site of the occlusion, as well as an increase in the intercoronary and intracoronary anastomoses. The granulomatous area never changes to scar tissue nor becomes avascular, because the irritant is never removed and it thus acts as a permanent source of collateral circulation The author has been able to demonstrate the permanency of the blood vessels in the granulomatous area as well as the continued presence of the irritant powder crystals by autopsy on patients who have died as long as 10 years after cardiopexy. The technique of cardiopexy has been described in detail (Thompson et al., 1954) and the following is a summary.

The approach to the heart is over the fifth left costal cartilage, which is removed. This approach is used because the pericardium is exposed without entering the pleural cavity. After a small opening is made in the pericardium, all fluid is aspirated to prevent the powdered talc from being washed to the dependent recesses of the pericardium. The irritant powder is then widely distributed over the anterior surface and borders of the myocardium No attempt is made to cover the posterior surface as some of the powder is carried there by the beating action of the heart. Surgery of coronary heart disease

ARTHUR M. VINEBERG

The treatment of coronary heart disease by medical or surgical means has been and still is most difficult—as well as unsatisfactory. This is attested to by the ever-increasing mortality and morbidity of the disease, which is now responsible for at least one in four deaths that occur in North America

As the disease is said to be unpredictable in its course, any form of treatment is difficult to evaluate. It has, in fact, been stated that "almost anything may cure precordial pain" This statement would be correct if it were modified to read, "almost anything may bring about temporary relief from precordial pain"

Credit for beneficial treatment, whether medical or surgical, has frequently been based upon sketchy pre- and postoperative evaluation of a patient's disease There are many reasons for this situation, mostly based upon misunderstanding, disagreement, and confused thinking. In this chapter, some of the thinking about the treatment of coronary heart disease will be reviewed so that, wherever possible, generally accepted facts may be listed, and the role of surgery in the treatment of coronary heart disease examined in their light

CORONARY CIRCULATION IN HEALTH AND DISEASE

The coronary circulation is different from that of any other circulating system in the human body It is necessary for all students of coronary heart disease to understand something about the complexity of the structure and function of the heart of man and lower animals In the past, there have been many disagreements concerning the character of the coronary circulation, particularly in reference to the anatomic vascular channels that lie within the ventricular myocardium and to their connections between the coronary and mediastinal vessels. During the past few years, a clearer picture has emerged, so that now there are certain facts about which there appears to be general agreement.

Two large arteries leave the aorta just above the right and left aortic cusps to form the main right and left coronary arteries, respectively.[1] The left coronary artery divides into the anterior descending septal and circumflex coronary branches. These large coronary arteries lie on the surface of the heart beneath the epicardium. Each large artery supplies a separate zone of arterioles lying within the myocardium Under normal conditions, there is little or no connection between the myocardial arteriolar zones supplied by the four major coronary arteries, it is for this reason that for many years the coronary arteries were considered to be end arteries [Fig 10-26(1)]. This view was tenable until Schlesinger and Zoll, through radiopaque injection studies of human coronary arteries, demonstrated the presence of numerous arteriolar-size branches running between different coronary arteriolar zones They found these communications to exist when there was narrowing or occlusion of coronary arteries in their epicardial courses. These types of communication between arteriolar zones or between arteries have been termed "collaterals" and have been shown to exist in 9 per cent of normal human hearts and in practically all human hearts with evidence of myocardial ischemia caused by coronary artery narrowing.

The "Collateral," Its Development and Distribution. For years physicians have been saying that if a patient is given time, he will develop his own collaterals and thus heal himself, further, that

[1] See Part 1, Chap. 6. *Editor.*

not been improved by as much as 50 per cent, and this is considered a poor result. The remaining 90 per cent of the patients show a minimum of 50 per cent improvement, and this is considered a good result. Some of the patients (40 per cent) are improved more than 75 per cent, and this is considered as an excellent result. Almost all the patients had sustained infarctions before the operation, and the vast majority were almost completely incapacitated.

In summarizing the surgical treatment of coronary disease and myocardial ischemias, two general principles are involved. One is palliative and consists of neurosurgical procedures. The other is definitive and consists in methods of myocardial revascularization. One of the simplest of these is cardiopexy. The mortality is low, and a 21-year follow-up shows the results are not surpassed by any other method.

In conclusion, it appears evident that the benefits to be obtained from surgery in cases of coronary disease and myocardial ischemia are rehabilitation, protection, and the prolongation of life.

arteriolar collaterals have developed to aid a more even distribution of blood throughout the heart muscle.

The problem thus resolves itself into a mechanical hydraulic one Coronary arteries *supplying blood to an area* of the myocardium have a well-established cross section which permits a maximum quantity of blood to flow through their channels into that area. It has been said that occlusion of one major coronary *artery* is necessary *to produce precordial* pain. It is evident that if one major coronary artery is occluded and another artery is somewhat narrowed, the third coronary artery cannot supply *the* amount *of* blood formerly *supplied by* the blocked *and narrowed* vessels This situation, therefore, results in either progressive slow death of the myocardium or sudden death in the form of myocardial infarction

The point of critical *coronary* artery *narrowing* has been clearly substantiated in the experimental laboratory at McGill University. It has been shown in animals that when two major coronary arteries, the anterior descending and circumflex arteries, are narrowed by ameroid constrictors to 50 per cent or more of their average lumens, the animals will die within a 28-day period In roughly 15 per cent of the animals, there is a large connection between the right and left *coronary arteries. In such* instances, the animals may survive partial constriction of their two major left coronary arteries. It is thus clear that ischemia in the human or animal heart stimulates *only the collaterals that lie* between the arteriolar zones and *between* coronary

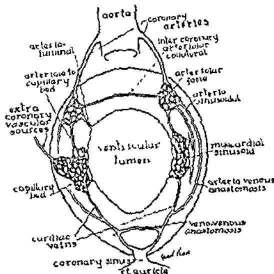

Fig. 10-26(4). *Myocardial circulation.*

arteries. There is no *evidence to indicate that in the diseased* human heart, *or in* the animal *heart* artificially made ischemic, there is an ingress of extracardiac arteriolar-sized blood channels into the myocardium.

The Myocardium as a Vascular Sponge. The vascular structure *of the myocardium* has been the subject of much controversy over the past 75 years Debate has centered on the existence or absence of (1) vessels in the heart walls communicat*ing* with the heart chambers; (2) vascular spaces *lying between myocardial fibers*, other than the capillary system.

Wearn, in a brilliant piece of work, clearly defined the relationship of thebesian arteriolumnal vessels *and myocardial sinusoidal spaces*. His conception of the vascular structure of *the myocardium* has been confirmed by others, including the author [Fig 10-26(4)] The concept of Wearn and the author concerning the structure of the coronary circulation, *if correct, permits of the theory* that the myocardium may obtain oxygenated blood from two sources, viz., (1) the coronary arterial tree, (2) the lumen of the ventricle. It is theo*retically possible for the* blood to be siphoned back into the ventricular wall *through arteriolumnal* and myocardial sinusoidal spaces during diastole, when such spaces are empty. This can happen *only in the diseased heart*, where there is little or no forward flow *into the myocardium* through the narrowed coronary arteries During *systole*, the vascular spaces of the myocardium are emptied by the squeezing action of the myocardial fibers and the blood is moved into the venous system [Fig 10-26(5)].

Myocardial sinusoidal spaces have *been frequently* shown in the author's laboratory. Because

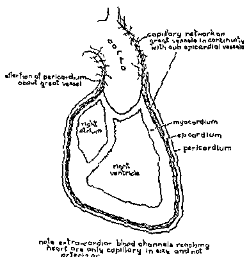

Fig. 10-26(3). *Type and course of mediastinal vessels entering heart.*

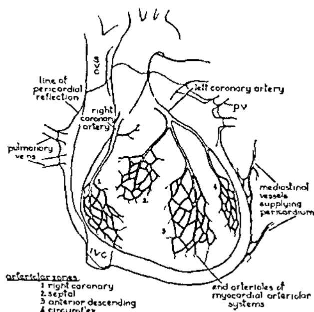

Fig. 10-26(1). Coronary artery distribution into separate arteriolar zones in normal heart.

patients have been known to live without any open coronary arteries whatsoever It is at this level that much clarification is needed

What do clinicians mean when they speak of "collaterals"? The majority of them picture blood vessels, from somewhere, reaching the ischemic areas of the myocardium This view is correct when it is confined to the opening up of communications between neighboring arteriolar zones within the confines of the heart, either upon its surface or within its musculature [Fig 10-26(2)]. It is badly founded when it suggests that extracardiac vessels of arteriolar size are capable of reaching the myocardium Both physiologists and pathologists have drawn attention to the blood vessels that reach the heart in the region of the pericardial reflection around the great vessels as they leave and enter the heart It has been suggested that collaterals may be established between the pericardial blood vessels and the heart via these routes

Evidence for the Presence of Extracardiac Channels. EPICARDIUM [2] The epicardium is composed of a thin layer of mesothelium, a simple squamous or cuboidal epithelium, together with a subjacent layer of fibroelastic connective tissue

CONNECTIVE TISSUE The connective tissue of the epicardium contains a considerable amount of fat, particularly in the region of the sulci and around the layer of vascular channels that lie over the surface of the ventricles It is continuous with the connective tissue forming the serosa of the great vessels entering and leaving the heart The deep layer of the epicardial connective tissue is continuous with the perimysium of the myocardium The perimysium is a dense layer of fibroelastic connective tissue that surrounds groups of muscle fiber bundles. In this layer is a network of blood and lymph capillaries and myocardial sinusoids.

There is thus no doubt that there is anatomic continuity between the capillaries of the serosa of the great vessels and those of the deeper layer of the epicardium. Many injection studies have shown connections between mediastinal vessels and the subepicardial vessels that reach the heart around the great vessels. These mediastinal myocardial-vascular connections have been frequently described, however, they have all been demonstrated by the injection of india ink or other fluid materials, and such injection studies prove very little except that a capillary network of vessels exists between the extracardiac vessels and the coronary vessels [Fig. 10-26(3)].

Of the numerous injection studies made by Schlesinger and Zoll, Blumgart and Zoll, and more recently by May, and others, there is no recorded evidence of arteriolar-size connections between the coronary arterial tree and the mediastinal vessels and the tissues surrounding the vessels that leave and enter the heart of man and animals. This is true of the human heart whether normal and healthy or diseased

The term "collateral vessel," therefore, must be reserved for arterioles that connect coronary arteriolar zones within the myocardium, it cannot be used to suggest the presence of, or the development of, extracardiac coronary arteriolar anastomoses.

The acceptance of this anatomic, pathologic fact makes it clear that *the myocardium can exist only on blood supplied by its own coronary arterial tree*

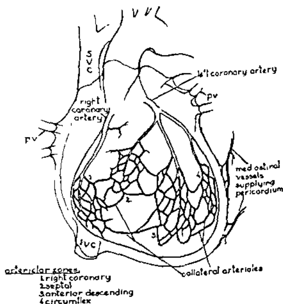

Fig. 10-26(2). *Arteriolar collateral development in ischemic heart*

[2] See Part 1, Chap. 5 *Editor.*

THE HEART The effect of coronary artery disease upon the heart is related to many factors, a great number of which are still unknown, and others unexplained. The myocardial fiber, which fundamentally is the unit of life, requires oxygenated blood in varying amounts. When a segment of myocardial fiber suffers diminution of blood supply because of narrowing of the supplying coronary artery, the area becomes anoxic. This may go unnoticed by the patient and, if it progresses, may result in the death of the affected area, forming a silent myocardial infarction. In most cases, however, the patient receives a warning of the area of myocardial ischemia and experiences precordial pain.

It is safe to say that precordial pain is generally accepted as a symptomatic reflection of myocardial ischemia caused by coronary artery insufficiency, and that when it occurs at least one major coronary artery is severely narrowed. When precordial pain persists in spite of medical therapy, there is no agreement as to the extent of myocardial fiber damage that may result. In the author's opinion, persistent precordial pain reflects continuous myocardial ischemia which results in progressive destruction of myocardial fibers.

Hill has shown that the longer the history of precordial pain is, the poorer the operative risk is and the less likelihood there is of a good result after revascularization.

Progressive destruction of myocardial fibers, whether due to chronic ischemia or to repeated acute myocardial infarction, usually leads to left ventricular failure. It may result in ventricular aneurysm, ruptured papillary muscle, or interventricular septal defect.

VENTRICULAR FIBRILLATION Another possible result of severe hypoxia or anoxia of the myocardial fiber is ventricular fibrillation. It has been shown by Beck that a small area of anoxia in the ventricular myocardium is sufficient to send the heart into ventricular fibrillation, with resultant death, unless the heart can be immediately defibrillated. Beck has frequently stated that these hearts "are too good to die." Immediate defibrillation has resulted in the resuscitation of a great number of patients who are living normal lives several years later.

Excluding the question of endocardial nutrition, the facts just mentioned have been proved by many and are now generally accepted.

SURGICAL PROCEDURES FOR THE TREATMENT OF CORONARY ARTERY DISEASE

Operative procedures are designed to (1) increase myocardial circulation, or (2) correct mechanical defects resulting from myocardial

Fig. 10-26(7). Myocardial sinusoidal space filled by injecting with india ink a human internal thoracic artery.

ischemia, such as left ventricular aneurysm, ruptured papillary muscle, or ruptured interventricular septum.

In the first group, it seems best, from a practical point of view, to list the various procedures under general headings according to the theoretical concept of their intended action and effect. These procedures are as follows.

SURGICAL PROCEDURES DESIGNED FOR THE CORRECTION OF CORONARY ARTERY INSUFFICIENCY

I Extracardiac procedures for pain relief
  A Neurosurgery to block afferent pain pathways
    1 Cervicothoracic ganglionectomy (Jonnesco, 1916)
    2 Chemical nerve block (Swetlow, 1926)
    3 Posterior rhizotomy (Hoven and King, 1942)
    4 Pericoronary neurectomy (Fauteux and Swenson, 1946)
  B Reduction of general metabolism
    1 Total thyroidectomy (Blumgart and Levine, 1933)
    2 Radioactive destruction of the thyroid gland
II Development of collaterals, anastomoses, or both
  A Ligation of cardiac vein (Fauteux, 1940)
  B. Ligation of coronary sinus (Gross and Blum, 1935)
  C Bilateral ligation of internal thoracic artery
  D Epicardiectomy and Ivalon sponge operation (Vineberg)
III Procedures to increase myocardial blood supply
  A. Bypass operations
    1 Myocardial vascularization by extracardiac blood

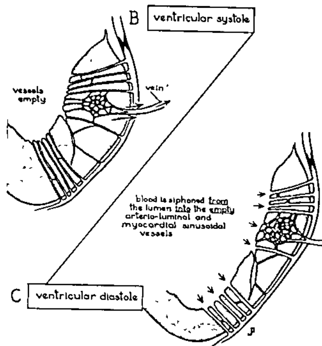

Fig. 10-26(5). Mechanism by which the vascular spaces of the myocardium are emptied and the blood is moved into the venous system

they exist, it has been possible to implant an open and bleeding systemic artery into the myocardial tunnel without formation of a myocardial hematoma. This has been performed many hundreds of times in the author's laboratory using the internal mammary artery. Others have had similar experiences with the splenic, carotid, or subclavian arteries. Such myocardial systemic arterial implants remain open because there is a satisfactory run-off through the myocardial sinusoidal and perhaps arterioluminal channels. A schematic drawing of such a mechanism is shown in Fig. 10-26(6). Figure 10-26(7) shows a myocardial sinusoidal space filled by injecting a human internal mammary artery, 82 hr after implantation, with india ink.

Surgical Pathology of Coronary Heart Disease. In surgery for coronary heart disease, consideration must be given to two major parts of the heart: (1) the part pertaining to the coronary arterial system, which perhaps may best be called *the myocardial circulation;* (2) *the heart itself,* in which the myocardium, the valves, and the papillary muscles may have become damaged.

THE CORONARY ARTERY SYSTEM AND THE MYOCARDIAL CIRCULATION. Atherosclerosis is a major disease affecting the coronary arteries. One rarely sees syphilitic aortitis which involves the coronary ostia. There are, however, other causes of coronary artery disease and of myocardial ischemia that are beyond the scope of this article. There is general agreement that atherosclerosis involves the arteries largely in their epicardial courses, leaving a vast arteriolar network within the myocardium comparatively disease-free.

Patients with severe diabetes and hypertension are the exception to the rule. In such patients, the smaller arterioles within the myocardium are much more likely to show atherosclerosis than in other patients without these two conditions.

A study of the distribution and extent of coronary artery atherosclerosis reveals that from 13 to 18 per cent of cases examined have segmental disease, i.e., isolated areas of occlusion or narrowing. These studies have been made at autopsy. It is probable that if more detailed coronary arteriography were available, the incidence of segmental coronary artery disease would be found to be higher, particularly in the younger age group.

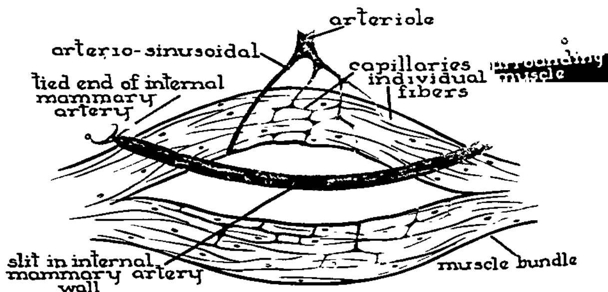

Fig. 10-26(6). Mechanism of internal thoracic artery branching within the myocardium.

results of these procedures are difficult to evaluate because the neurosurgical reports deal largely with pain, its relief, and neurosurgical techniques. Very little is mentioned in regard to the type of condition for which the patient is operated upon.

CERVICOTHORACIC GANGLIONECTOMY. Lindgren treated 105 patients by cervicothoracic ganglionectomy (*operative mortality, 8.5 per cent*). The anterior *approach* was used in *stages* 2 months apart; the stellate and upper T_4 and T_5 ganglia were removed bilaterally. Pain was relieved in 75 per cent of patients, with 66 per cent reporting an increased capacity for work. A warning signal still remained. There was no evidence *of prolongation of life.*

POSTERIOR RHIZOTOMY. This procedure involves section of the posterior sensory nerve roots and of the upper four or five thoracic nerve roots.

White reports 31 cases collected from different centers, with 3 *operative deaths,* and with complete relief of pain in all but 2 patients. The advantages of this procedure are the following: (1) there is no possibility of regeneration; and (2) the fibers can be cut at both ends at the same operation. The disadvantages are (1) *it is a major procedure on* bad-risk patients, (2) bilateral laminectomy involving four vertebrae, a time-consuming procedure, is necessary, (3) there is danger of ischemia, transverse myelitis, and anoxia owing to the prone position.

PERICORONARY NEURECTOMY. This procedure involves *paravertebral alcohol injection* of the upper thoracic sympathetic ganglia.

> White has treated 77 patients with precordial pain with 100 alcohol injections, with *no major or serious complications.* He reports that 62.3 per cent of patients experienced complete relief of pain on the side of denervation, 20.8 per cent were improved, 7.8 per cent of the *attempts failed,* and there was a 9.10 per cent death rate. In the hands of others, chemical block of afferent pathways has *not been so successful.*

The disadvantages of this procedure are as follows. (1) it has failed to control pain in at least 10 *per cent of cases* and there has been an 18 per cent recurrence rate within 2½ months, (2) the injections, started *under local* anesthesia to detect Horner's syndrome and outline the absence of sweating, may be painful, (3) spinal cord surgery may produce a resultant myelitis; (4) deaths have occurred; (5) intercostal neuralgia may be *troublesome* and may last a long time.

> White suggests use of cardiac denervation for precordial pain in the following groups of patients: (1) those with severe "angina decubitus," to forestall drug addiction and give some relief, (2) those *who cannot* tolerate hyperthyroidism; (3) those with aortic insufficiency and syphilitic aortitis who have precordial pain.

Certainly the paravertebral injections of alcohol, as carried out by White, seem to be worthwhile in bed-rest patients with severe precordial pain.

Development of Collaterals, Anastomoses, or

Both

tion

bilat

Gross ... nary sinus ligation would hasten the physiologic process of aging by the formation of collaterals. Both the procedures of great cardiac vein ligation and coronary sinus ligation in the treatment of coronary artery disease are based *upon this concept.*

Fauteux (1939–1940) reported *a protective* effect against anterior descending branch ligation after cardiac vein ligation, which persisted up to 1 year in animals; in 1946 he reported his results in 10 patients with precordial pain, 7 of whom had returned to work. Ripstein *(1948) analyzed* the results of 40 cases and reported that 72 *per cent* of the group had benefited from the procedure.

LIGATION OF CORONARY SINUS. Total ligation of the coronary sinus *frequently* causes marked venous congestion and turgidity of the ventricular wall. For this reason, Beck modified *the operation by tying* the coronary sinus at its entrance to the right *atrium around* a 3-mm probe. Beck is of the opinion that by *this* means, intercoronary collaterals are opened and a wider distribution of blood is brought about throughout the ventricular myocardium. In the past *few years,* he has performed this operation upon patients suffering from coronary artery insufficiency. The *partial ligation of the coronary sinus* is supplemented by *abrasion of the epicardium and inner surface of the pericardium* with a mechanical abrader and by the introduction *of* asbestos powder between the heart and the pericardial fat pads that are sutured directly to the heart muscle. This operation is

2. Surface grafts
   a. Pectoral muscle (Beck, 1935)
   b. Omentum (O'Shaughnessy, 1936)
   c. Lung (Lezius, 1937; Carter, 1949)
   d. Lung and ligation of pulmonary artery (Liebow, 1950)
   e. Pericardial fat pad (Vineberg, 1954)
   f. Skin (Moran, 1952)
   g. Jejunum (Key, 1954)

B. Arterialization of coronary sinus (Beck, 1948)

C. Cardiopericardiopexy
   1. Bone, chips, asbestos, etc (*Feil and* Beck, 1937)
   2. Talc (Thompson, 1939)

D. Ventricular arterialization by vascular implants
   1. Internal thoracic artery implant (Vineberg, 1946–1961)
   2. Splenic artery implant (Liebow, 1956)
   3. Carotid artery implant (Sabiston and Blalock, 1956)

E. Graft from aorta to myocardium
   1. Single (Vineberg and McIntosh, 1954–1957; Sabiston and Blalock, 1956; Smith, 1957)
   2. Double (Vineberg and Duchesne, 1957)

IV. Myocardial circulation from the left ventricular lumen
   A. Epicardiectomy
   B. Epicardiectomy and Vineberg sponge operation
   C. Direct tapping of left ventricle (Vineberg-Massino)

V. Direct attack upon the coronary arteries
   A. Endarterectomy (May, Bailey, Sabiston, Longmeyer)
   B. Endarterectomy with patch graft (Senning)
   C. Resection *segments with end-to-end anastomoses* with or without graft (Robb)
   D. Systemic artery to distal end of coronary artery (numerous workers)

From the above list, it is evident that many different attempts have been made to treat coronary heart disease surgically. A careful examination of the experience with each procedure reveals the shocking fact that few of them have had adequate experimental background before their application to human beings. The author has frequently stressed the importance of the experimental laboratory in assaying a surgical procedure. This view has not been and is still not universally held. Yet those who criticize animal experimental evidence as being *valueless because of the differences* between human beings and lower animals are the first to try out a new surgical procedure based on a theoretical but unproved concept. It is quite true *that that which is of value in an animal may* not be of value in a human being, it is just as true, however, that a procedure that has not worked in a lower animal is not likely to do so in man.

In *the light of recent knowledge of coronary* heart disease, it is clear that surgical procedures designed for the treatment of this disease should have certain clearly defined objectives and should be based on the known *physiologic and pathologic* facts.

Objectives of Surgery

1. To relieve precordial pain
2. To relieve right and left ventricular failure
3. To correct mechanical defects produced by myocardial ischemia
4. To increase exercise tolerance and ability to work
5. To prevent further loss of myocardial fibers
6. To prolong life expectancy

Each surgical procedure should be carefully scrutinized to judge whether it is capable of fulfilling the six objectives and is supported by adequate experimental and pathologic evidence.

Neurosurgery to Block Afferent Pain Pathways. INTERRUPTION OF CARDIAC PAIN FIBERS. The following procedures were designed to relieve precordial pain: cervicothoracic ganglionectomy, chemical nerve block, posterior rhizotomy, and pericoronary neurectomy.

When Jonnesco (1916) performed a trial *DI-5 sympathectomy for the relief of precordial* pain, there was little understanding of the mechanism or cause of this type of pain. There never was any question that the circulation in the myocardium would be improved, because it was not until 1928 that the mechanism of pain was clearly explained by Keefer and Resnick. *These authors* crystallized the concept that *precordial pain is due to a relative disproportion between myocardial demand for oxygen and its supply*

Neurosurgeons favor the neurosurgic treatment of precordial pain for the following reasons (1) the cutting of sensory nerves interrupts nerve pathways, (2) severance of motor acceleration nerves interrupts cardiopressor reflexes, (3) cutting of vasomotor nerves theoretically stops vasoconstrictor impulses to coronary arteries, thus permitting development of collateral circulation.

J. C White points out that "all cardiac pain *fibers function* from the upper three or at most four thoracic ganglia to reach the sensorium over the corresponding white rami communicantes, small nerves and their posterior nerve roots" These *fibers can be interrupted* by chemical injection of the four upper thoracic ganglia and their *rami* communicantes, resection of these ganglia without removal of the sympathetic chain, and interruption *of the upper four* posterior spinal nerve roots. The

results of these procedures are difficult to evaluate because the neurosurgical reports deal largely with pain, its relief, and neurosurgical techniques. Very little is mentioned in regard to the type of condition for which the patient is operated upon.

CERVICOTHORACIC GANGLIONECTOMY. Lindgren treated 105 patients by cervicothoracic ganglionectomy (operative mortality, 8.5 per cent). The anterior approach was used in stages 2 months apart; the stellate and upper T_4 and T_5 ganglia were removed bilaterally. Pain was relieved in 75 per cent of patients, with 66 per cent reporting an increased capacity for work. A warning signal still remained. There was no evidence of prolongation of life.

POSTERIOR RHIZOTOMY. This procedure involves section of the posterior sensory nerve roots and of the upper four or five thoracic nerve roots.

White reports 31 cases collected from different centers, with 3 operative deaths, and with complete relief of pain in all but 2 patients. The advantages of this procedure are the following: (1) there is no possibility of regeneration; and (2) the fibers can be cut at both ends at the same operation. The disadvantages are (1) it is a major procedure on bad-risk patients, (2) bilateral laminectomy involving four vertebrae, a time-consuming procedure, is necessary, (3) there is danger of ischemia, transverse myelitis, and anoxia owing to the prone position.

PERICORONARY NEURECTOMY. This procedure involves paravertebral alcohol injection of the upper thoracic sympathetic ganglia.

White has treated 77 patients with precordial pain with 100 alcohol injections, with no major or serious complications. He reports that 62.3 per cent of patients experienced complete relief of pain on the side of denervation, 20.8 per cent were improved, 7.8 per cent of the attempts failed, and there was a 9.10 per cent death rate. In the hands of others, chemical block of afferent pathways has not been so successful.

The disadvantages of this procedure are as follows: (1) it has failed to control pain in at least 16 per cent of cases and there has been an 18 per cent recurrence rate within 2½ months, (2) the injections, started under local anesthesia to detect Horner's syndrome and outline the absence of sweating, may be painful, (3) spinal cord surgery may produce a resultant myelitis; (4) deaths have occurred; (5) intercostal neuralgia may be troublesome and may last a long time.

White suggests use of cardiac denervation for precordial pain in the following groups of patients: (1) those with severe "angina decubitus," to fore- [illegible] have precordial pain.

Certainly the paravertebral injections of alcohol, as carried out by White, seem to be worthwhile in bed-rest patients with severe precordial pain.

Development of Collaterals, Anastomoses, or Both. The following procedures are used: ligation of cardiac vein, ligation of coronary sinus, bilateral ligation of internal thoracic artery.

Gross and Blum (1935) suggested that coronary sinus ligation would hasten the physiologic process of aging by the formation of collaterals. Both the procedures of great cardiac vein ligation and coronary sinus ligation in the treatment of coronary artery disease are based upon this concept.

Fauteux (1939–1940) reported a protective effect against anterior descending branch ligation after cardiac vein ligation, which persisted up to 1 year in animals; in 1946 he reported his results in 10 patients with precordial pain, 7 of whom had returned to work. Ripstein (1948) analyzed the results of 40 cases and reported that 72 per cent of the group had benefited from the procedure.

LIGATION OF CORONARY SINUS. Total ligation of the coronary sinus frequently causes marked venous congestion and turgidity of the ventricular wall. For this reason, Beck modified the operation by tying the coronary sinus at its entrance to the right atrium around a 3-mm probe. Beck is of the opinion that by this means, intercoronary collaterals are opened and a wider distribution of blood is brought about throughout the ventricular myocardium. In the past few years, he has performed this operation upon patients suffering from coronary artery insufficiency. The partial ligation of the coronary sinus is supplemented by abrasion of the epicardium and inner surface of the pericardium with a mechanical abrader and by the introduction of asbestos powder between the heart and the pericardial fat pads that are sutured directly to the heart muscle. This operation is

known as *the Beck I operation* and is now performed on patients with coronary artery disease in many centers, with reported good results.

BILATERAL LIGATION OF INTERNAL THORACIC ARTERIES. The rationale of the operation is based upon the known presence of capillary-sized anastomotic channels between the pericardiophrenic arteries and the coronary circulation through the pericardial fat pads and pericardial reflections over great vessels. This anastomotic bed is, as has been pointed out, entirely capillary in nature. According to the proponents of this operation (Battezzati et al., 1955), bilateral ligation of the internal thoracic arteries at the 2d interspace increases the rate of blood flow down the pericardiophrenic artery, thus causing blood to flow into the coronary artery bed.

A large series of patients operated upon by different European surgeons, particularly Italian, was reported in Turin, Italy, in which results have been stated to be excellent. However, in no instance has any one of these surgeons showed objective evidence that bilateral internal thoracic artery ligation opened up or developed extracardiac arteriolar-sized channels which communicated with the vessels of the myocardium. Although this operation is still being performed and reported in Europe, there is fundamentally no anatomic, physiologic, or experimental evidence to warrant its continued use in human beings. Some Russian surgeons have even combined the internal thoracic artery ligation operation with cardiopericardiopexy in the treatment of acute myocardial infarction. The results of this operation, as performed in North America and reported upon by surgeons from this continent, have not lived up to early expectations. Further, the North American workers, like the European surgeons, have not brought forth any evidence to show that the operation permits extracardiac channels of arteriolar or larger size to develop between the mediastinal vessels and the myocardium.

Myocardial Vascularization by Extracardiac Blood. Coronary artery narrowing, resulting in myocardial ischemia, usually occurs in the epicardial parts of the coronary vessels, leaving the arteriolar system lying within the myocardium comparatively intact. Surgical revascularization methods attempt to bypass points of coronary artery obstruction by connecting an extracardiac source of blood to the ventricular myocardium distal to these points of obstruction. Theoretically this is a sound concept, based upon the pathologic state that exists in human coronary artery disease. Practically, it has presented most difficult and perplexing problems, particularly in reference to (1) introduction of a volume of blood large enough to relieve myocardial ischemia, (2) equal distribution of the extracardiac blood throughout the myocardium, and (3) maintenance over months and years of the new extracardiac source of blood pathways.

SURFACE GRAFTS. Many types of tissue have been grafted to the surface of the left ventricle in the hope that these grafts would furnish the myocardium with a fresh extracardiac source of oxygenated blood.

Beck attached the left pectoralis major muscle to the surface of the left ventricle. This operation has been performed on animals, and on a few human beings, with *questionable results*. Many other types of surface grafts have also been employed.

O'Shaughnessy (1936–1937) brought a vascular flap of omentum up through the diaphragm and affixed it to the anterior surface of the left ventricle, where it formed anastomotic channels between the vessels of the omentum and the heart. Of 12 patients operated upon, 8 survived, 7 of the survivors continued to show increasing improvement. This operation has been performed twice by the author, without beneficial results but without mortality. One of the two patients had many gastrointestinal tract disturbances (*this apparently is one* of the complications experienced by O'Shaughnessy's patients). In addition, this operation has been criticized because of its combined abdominothoracic approach and because proper visualization of the pathologic changes in the heart cannot be achieved. It is no longer employed clinically.

Cardiopneumopexy. Lezius (1937) used the lower and middle lobes of the left lung and grafted them to the myocardial surface in animals. This method of myocardial revascularization was further explored by Carter et al.

Both Lezius and Carter demonstrated blood vessel channels between the pulmonary and coronary vessels, but information concerning the direction of blood flow, the volume of blood delivered through the new channels, and the duration is not available. This method has been criticized by Ghinst because it can deliver only unoxygenated blood; he further stated that the pulmonary vessels communicated with myocardial venous, not arterial, channels. Carter used this method in the treatment of coronary artery insufficiency in two patients, one of whom died, the other is said to have done well. Liebow et al modified this pro-

cedure by first ligating the arterial blood supply to the lingula; they then painted phenol on the mediastinal surface of the lingula and upon the ventricle before suturing the lingula to the surface of the left ventricle. In these experimental animals, they have produced evidence to indicate that the bronchial arteries to the lingula grow down the bronchus and eventually anastomose with the coronary vessels. This is an intriguing method of revascularization and may prove useful in the treatment of coronary artery disease in human beings.

Pericardial Fat Pad Grafts. In this operation, the medial diaphragmatic and phrenic fat pads are detached from the fibrous pericardium. The epicardium covering the surface of the myocardium is then removed by sharp dissection, and the fat pads are applied to the surface of the heart (Vineberg).

It has been shown by Vineberg et al and by Martineau that in the partially ischemic heart, arteriolar communication develops between the grafted pericardial fat pads and the coronary circulation Further, in one patient, 18 months after operation, retrograde injection of the circumflex artery showed the injection mass to enter the diaphragmatic fat pad Pericardial fat pad grafts, as a supplement to internal thoracic artery implant, have been used by the author since 1953 wherever possible

It may be that the major benefit derived from the Beck I operation is due to the introduction of extracardiac blood through the pericardial fat pads, which are applied to the surface of the heart after partial ligation of the coronary sinus, instrumental epicardial scraping, and irritation with asbestos powder

Skin Pedicle and Jejunum Grafts. Other surface grafts, which have been attempted in animals, include a skin pedicle flap, described by Moran et al (1952), and a jejunum graft, by Key et al (1954)

Key and coworkers report that in 75 per cent of their cases the jejunal pedicle vessels were open, while in 81 per cent there were anastomoses between the jejunum and the coronary vessels The type of anastomosis was almost entirely capillary, but they suggest that the amount of blood delivered through multiple capillary anastomoses would equal that produced by several small arteries Survival from anterior descending branch ligation was 93 1 per cent in grafted dogs, as compared with 28.7 per cent in control animals.

The jejunal graft is probably too major a procedure to be used in the treatment of human beings with coronary artery disease, since it involves, as does cardioomentopexy, an abdominothoracic approach.

ARTERIALIZATION OF THE CORONARY SINUS. Batson (1931) demonstrated that the heart can be kept alive and beating in an isolated state by perfusing it through the coronary venous system. This observation, corroborated by many workers, led to the idea, first described by Roberts et al. (1943), of anastomosing an artery to the coronary sinus, using the subclavian and brachiocephalic (or innominate) arteries.

Beck (1948) reported revascularization of the heart by grafting a systemic artery into the coronary sinus; he then modified it to a two-stage procedure known as *the Beck II operation*

In the first stage of this operation, anastomosis between the coronary sinus and the aorta is made by means of a jugular vein graft, and a ligature is placed around the coronary sinus just before its entrance into the right atrium Then, 3 to 6 weeks later, this ligature is partially closed at the second operation. Seven patients with coronary artery insufficiency were operated upon with a high mortality. Bailey modified the procedure and operated upon a comparatively large number of patients. He reports a total experience with 71 patients, 53 of whom had the Beck II operation, there were 8 deaths, and 8 blocked grafts were found at the second stage of the operation. The final results on these patients have not yet been published. Eighteen patients had Kralik's modification of Beck's procedure; again, the mortality and final results are not available.

The Beck II operation has been given up by Beck and by others because of its high mortality and because it was shown (Eckstein et al.) that retrograde perfusion of the coronary bed or through the graft lasts only for about 5 weeks; functional contact with the bed is then lost, probably because of obliterative venous change caused by high arterial pressure in the venous bed.

VENTRICULAR ARTERIALIZATION BY VASCULAR IMPLANTS. The implantation of a systemic artery into the left ventricular myocardium was first attempted by the author (1945).

The internal thoracic artery was detached from the chest wall between the 6th and 4th interspaces, it was divided between ligatures, and the proximal end was buried within a tunnel made in the myocardium. In its new location, the transplanted

vessel remains open because of side branches which are left open at the time of implantation and which bleed into vascular spaces surrounding the internal thoracic artery within the tunnel. The implanted vessel commences to bud at the end of 12 days, and, between 3 and 6 weeks, it sends out numerous arteriolar or larger branches which anastomose with the surrounding arteriolar network lying within the myocardium. When these thoracic-coronary anastomoses occur, which they do in 94 per cent of canine hearts made ischemic by ameroid constrictors placed on the coronary vessels, systemic arterial blood is propelled from the subclavian artery down the internal thoracic artery into the myocardial arteriolar network. There, it is distributed at first to the anterior portion of the myocardium and then, gradually, over a period of 5 months, as the ischemia progresses, to the entire left ventricle. Through these thoracic-coronary anastomoses, a rate of blood flow into the heart as high as 55 ml/min has been measured.

Sixty per cent of the arterial blood introduced through the internal thoracic artery 5, 6, and 7 months after implantation has been recovered from the coronary sinus, indicating that blood introduced through the implanted internal thoracic artery reaches the ventricular myocardial fibers.

It has been shown, both in animals and in man, that if there is myocardial ischemia, the implanted vessel, studied 6 months to 3 years after implantation, has remained patent and does not close off by intimal proliferation.

Many other workers obtained similar results with internal mammary artery implantation when the techniques outlined by the author were carefully followed. More recently, similar results have been obtained by Liebow, who implanted *the splenic artery* into the myocardium, and by Sabiston and Blalock, who have implanted *the carotid artery* in animals. Others, including the author, have used in animals the same principles to implant free homologous arterial grafts, which are attached at one end to the aorta Smith has substituted homologous grafts for nylon tubes, and has performed a nylon tube implant in human beings with coronary artery disease

The principle of internal mammary artery implantation is based upon two pathologic facts: (1) that coronary artery disease involves mainly the epicardial branches and, in particular, the first 3 to 4 cm of the origin of the main vessels; (2) that extensive intercoronary arteriolar anastomosis is present when myocardial ischemia develops because of coronary artery stenosis. Thus, the internal mammary artery, or any other vascular implant, bypasses the points of coronary artery obstruction to pour systemic extracardiac arterial blood into the ventricular myocardial arteriolar network. Once there, because of collateral arteriolar branches, the blood should reach all parts of the left ventricular myocardium.

Many hundreds of animals have undergone internal mammary artery implant, and well over 100 patients with coronary artery insufficiency have thus been treated The results have been most encouraging and will be discussed below.

Myocardial Circulation from Left Ventricular Lumen. The early, primitive reptilian creatures had no coronary arteries. The hag fish, which still swims in the South Pacific ocean, a 400-million-year-old prehistoric creature, has a systemic heart in which there are no coronary arteries and no nerve supply: the myocardium of the systemic heart receives nutrition through channels which communicate with the lumen of the ventricle. The mechanism of the myocardial circulation is that of ebb and flow, similar to a bathroom sponge being squeezed and relaxed. In our laboratory, we have been able to show that a beating heart in the animal can and will siphon Schlesinger mass from the left ventricular lumen when its two major coronary arteries are cut if it has had a previous epicardiectomy or an epicardiectomy plus the Vineberg sponge operation

Experience with patients undergoing the Vineberg sponge operation has disclosed that (1) the [illegible]

(3) these hearts enlarge These three facts suggested that the beating, ischemic left ventricle of the human heart, in the presence of occluded, or nearly occluded, coronary arteries can and does siphon blood from its own left ventricular cavity after removal of the epicardium [Fig 10-26(8)] These experimental and clinical observations become extremely interesting if an analysis is made of some of the operative procedures that have been used in the treatment of coronary artery insufficiency Thus, we find that in the Beck I operation, which has a good record of satisfactory results, the first stage is epicardiectomy, followed by partial ligation of the coronary sinus, and then by the application of pericardial fat pads to the left ventricular myocardium; before this is done, asbestos powder is sprinkled over the surface of the heart. The sprinkling of asbestos powder, in the author's belief, negates the value of the epicardiectomy. as

time goes on, scar tissue is formed, which prevents the myocardium from maintaining the loosened structure caused by epicardiectomy; thus, the numerous luminal myocardial vascular spaces, which were opened following *epicardiectomy*, tend to be *squeezed* closed again by the constricting scar tissue, which develops as the result of the use of asbestos powder. When epicardiectomy is performed, the heart enlarges *This enlargement* allows the *400-million-year-old* arterial luminal, luminal myocardial, and myocardial sinusoidal spaces to enlarge and to siphon blood into their spaces from the lumens of the left ventricle during diastole

When a sheet of Ivalon sponge is placed upon the bared left ventricular myocardium, this sheet tends to keep the myocardium in the same condition as it was at the time of application of the Ivalon sponge. It does not cause contraction, such as *that due to the application of asbestos or* talc, but rather maintains the status quo

Direct Attacks on the Coronary Arteries. CORONARY ENDARTERECTOMY. This procedure has been performed on a few patients. Unfortunately to date the mortality has been high and the end results have *not* been too satisfactory. However, with the introduction of better visualization of segmental coronary artery disease, the use of extracorporeal circulation, and hypothermia, it may be that this procedure will have its place in the *treatment* of coronary artery disease.

Endarterectomy combined with patch graft, as suggested by Senning, seems more promising than endarterectomy alone. It would seem to prevent reocclusion of the artery and offers a better chance for removal of the atheromatous material *from the artery and its penetrating* branches

Resection of segments—end-to-end anastomoses, with or without graft—has not been attempted on human beings This is still a laboratory procedure. The introduction of a systemic artery into the distal open end of a coronary artery is likewise a laboratory procedure but may be of value in the future

SELECTION OF OPERATIVE PROCEDURE

It is the author's belief that surgery of coronary artery disease, like surgery of a peptic ulcer, will make use of many methods and techniques Some years ago, surgeons argued as to the best technique for removing the stomach in the treatment of duodenal ulcer. Their medical confreres were arguing that surgery was of no use as a cure for peptic ulcer. Today there are few *who do not admit the value of* some *form of gastrectomy* in the treatment of intractable peptic ulcer. There is no further discussion as to what technique will be used, the surgeon has at his disposal numerous operative techniques and he tailors his operative procedure to suit the peculiarities of the case. Thus, it would seem that the selection of an operative procedure *for coronary artery disease* will depend upon the pathologic change that has occurred in the particular patient. For example, if, in the near future, it is shown in a young patient that the disease is segmental, very likely *endarterectomy* will be performed. If the disease is shown to be far advanced, with multiple lesions, *one of the bypass operations* will be used. Likewise, if the heart is in chronic failure, then it would seem that the *Vineberg sponge operation* or some modification of this operation, such as tapping *of the left ventricle*, may be used

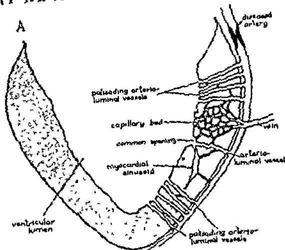

Fig. 10-26(8). Theoretical mechanism of endocardial nutrition in the ischemic heart after Ivalon sponge operation

However, whichever of these operations is chosen, it is the author's belief that proof should be shown that *surgical revascularization* has produced channels of arteriolar size between the coronary circulation and the extracardiac source of blood. These anastomotic channels should be large *enough to supply* the myocardium with as much blood as is *normally supplied by the left* coronary artery, and should be present for at least *6 months* or longer. The quantity of extracardiac blood de-

livered to the myocardium through the anastomotic channels should be sufficient to relieve myocardial ischemia at rest and under stress. The patient should survive without infarction after ligation of one or more major coronary vessels. Removal of the extracardiac source of blood after ligation of the anterior descending branch should result in death or infarction. Coronary artery sclerosis and occlusion should be produced and should be treated by the introduction of a fresh extracoronary source of blood. Blood flow measurements and oxygen-consumption studies should be made in order to determine the amount of blood and oxygen delivered to the heart. Anterior and circumflex coronary arteries should be gradually occluded as a means of producing left ventricular ischemia, and an evaluation of the revascularization procedure in the protection of the myocardium should be made under such conditions.

An operative procedure that experimentally fulfills the above criteria should theoretically be capable of attaining the following objectives, which, as pointed out earlier in this chapter, form the basic aim in treating coronary artery disease by surgical means (1) relief of precordial pain, (2) increase of exercise tolerance and ability to work, (3) prevention of further myocardial fiber loss, (4) prolongation of life expectancy, and (5) low operative mortality

A careful study of the various surgical procedures that have been outlined reveals that at present only three of them have extensive laboratory proof of value These are the Beck I, the Vineberg internal thoracic artery implantation, and the Vineberg sponge operations

SELECTION OF PATIENTS

In 1950 the author, like other surgeons in the field of coronary artery surgery, was given no opportunity to select patients Cardiac surgery, of any type, was considered highly experimental and extremely hazardous The only patients reporting for surgery were desperate, disabled, and pain-ridden persons, a large percentage of whom were bed-chair invalids Experience showed that the proper selection of patients for surgery should depend largely on the stage of development of the patient's disease, and the following criteria were agreed upon.

Indications for Surgery. PROVED CORONARY ARTERY DISEASE, WITH TYPICAL PRECORDIAL PAIN. The presence of proved coronary artery disease in itself is not sufficient indication for surgery unless the patient suffers from precordial pain which is truly causing difficulty. The author and his medical associates are firmly convinced that the occurrence of occasional precordial pain after unusual physical effort or excitement does not warrant a major surgical operation. Such a patient should be advised to forego the extra nine holes of golf. This point of view, however, is not subscribed to by Brofman and Beck, who believe that the presence of coronary artery disease in itself is an indication for surgery, even though the patient may be asymptomatic.

FAILURE TO IMPROVE ON MEDICAL TREATMENT OVER A PERIOD OF 1 TO 2 YEARS The question is: If one does not operate upon a patient with coronary artery disease who is asymptomatic, or who has occasional pain only, at what stage in his disease should surgery be performed? There is a great divergence of opinion on this point. The author's group, however, has elicited evidence that would seem to indicate *that operation should be performed on those patients who have failed to show improvement and whose pain causes disability after an adequate medical regime of 1 to 2 years' duration*

TWO CORONARY OCCLUSIONS WITH MYOCARDIAL INFARCTION. Patients who have had two or more coronary artery occlusions with infarction, even though they may be asymptomatic, have such a poor outlook for survival that some cardiologists are of the opinion that they should be accepted for surgery.

VENTRICULAR FAILURE, RIGHT AND LEFT, WITH OR WITHOUT PRECORDIAL PAIN.

Contraindications for Surgery. ASYMPTOMATIC CORONARY ARTERY DISEASE. As mentioned above, not all investigators consider this a contraindication.

RECENT INFARCTION, OR EVIDENCE OF DISEASE ACTIVITY Most cardiac surgeons and cardiologists are agreed that a period of 6 months should elapse after infarction before surgery is considered. This view, however, is not accepted by all. Smith operated, with what appeared to be a good result, on a patient who had had two recent myocardial infarctions.

MARKED ENLARGEMENT OF THE LEFT VENTRICLE The enlarged left ventricle may represent dilatation due to failure, hypertrophy due to myocardial ischemia, or a combination of both. In any of these cases, the Vineberg

sponge operation may be helpful. However, if the left ventricle is enlarged because of severe hypertension, it is questionable, because of numerous diseased arterioles within the myocardium, whether the patient should undergo any form of revascularization surgery.

RAPID PROGRESSIVE DETERIORATION. Many surgeons prefer to wait for some degree of stabilization in these patients. Not infrequently, the augmentation of precordial pain may be a precursor of coronary artery thrombosis and infarction. Such patients may die in the anesthesia room, on the operating table, or shortly thereafter, from an exacerbation of their disease.

MALIGNANT HYPERTENSION, SEVERE DIABETES, OR OTHER INCURABLE DISEASES

THE "ANGINA DECUBITUS" GROUP. This group consists of patients who suffer pain at rest without exciting cause. Patients who experience night pain or pain at rest while watching television or after eating, do not necessarily have angina decubitus. Patients with true angina decubitus should not undergo revascularization surgery, the mortality is high and the end results are poor in those who survive operation. Pathologic examination of the hearts of patients who have died from angina decubitus reveals that such patients generally were living with one pin-point opening, or perhaps two, in their major coronary arteries. There is insufficient coronary circulation to carry such patients through anesthesia without left ventricular failure, ventricular fibrillation, or a fresh coronary thrombosis within 3 weeks of surgery. Further examination of such hearts shows that, because of the prolonged period of ischemia, which in the author's series was well over 10 years, there is little myocardial muscle fiber left to revascularize.

The view that surgery is contraindicated for patients with angina decubitus has been queried by some, who are unwilling to suggest surgery to patients with less advanced disease, still able to get along with an occasional nitroglycerin tablet. This is similar to suggesting that a patient with mitral stenosis who is doing well on digitalis does not require mitral commissurotomy. Unquestionably such patients do well for a while without commissurotomy, but it is well known that the death and complication rate of patients with mitral stenosis mounts steadily with each succeeding year that surgery is postponed. The same is true of coronary heart disease. The longer the disease process is active, the greater the danger for the patient.

The recent report of White et al. on a 25-year follow-up of patients with myocardial infarction can be used as a guide in the selection of patients for revascularization surgery. To quote these authors, "The best aid to long term progress following myocardial infarction is the degree of recovery of the patients following the acute period of illness." In their patients who had complete medical recovery following infarction, 82 per cent were alive at the end of 5 years, whereas of the entire group of 162, only 49 per cent were alive 5 years after myocardial infarction.

Although patients with precordial pain without infarction appear to have a better future, White states that the mortality in patients with coronary disease who have pain is usually 7 per cent above the expected mortality. The asymptomatic patient, therefore, has a better prognosis, the hearts of such patients being well taken care of by their undiseased "good-neighbor" arteries, which are known to send collaterals to the ischemic zone, so that there is no need for extracardiac sources of blood. Any type of revascularization surgery upon such patients can do no more than nature has already done.

PREOPERATIVE INVESTIGATION AND POSTOPERATIVE CARE

Diagnosis. Preoperative investigation is absolutely essential, in order to establish a firm diagnosis and to ascertain the presence or absence of other disease or condition that might be the source of the patient's symptoms.

In general, chest pain that is not initiated by physical activity or emotion and does not disappear rapidly with rest should be regarded with suspicion. Generally, a pain of long duration that is not made worse by exercise and is not relieved by nitroglycerin, is not caused by myocardial ischemia. A search for hiatus hernia, biliary tract disease, peptic ulcer, and even cervical or upper thoracic disks may disclose the source of the pain. The ECG is of value when it is positive. Failure to obtain electrocardiographic evidence of coronary artery disease with the Master's two-step test or the treadmill exercise may leave the diagnosis in doubt.

Roentgenology. During the past few years, it has become possible to outline the coronary arterial tree. It is the author's opinion that in all patients being considered for surgical treatment of coronary artery insufficiency, the degree and location of occlusion of the coronary arterial tree should be outlined by one of the numerous techniques now available. Only by *coronary arteriography* is it possible to decide whether the patient has any coronary artery disease. Frequently in the author's clinic, patients have had clinical histories strongly suggesting that they were suffering from coronary artery insufficiency; yet the coronary arteriogram has failed to show any evidence of disease. Such patients have not undergone any form of surgery.

It is the author's belief that if one coronary artery is narrowed but two major coronary arteries are free of disease, the patient will probably develop intercoronary collaterals, which will bring blood from the normal coronary arteries into the area supplied by the narrowed diseased vessel. If such a patient fails to improve clinically, one should resort to operation not only to introduce extra blood but also to cause a good distribution of the blood that has been introduced through the two good coronary arteries

If two major coronary arteries have been narrowed to an average cross-sectional area of 50 per cent or more of their combined luminal areas, a point of critical narrowing has been reached, and the patient, in the author's opinion, is in danger of ventricular fibrillation or myocardial infarction Such patients should undergo surgical intervention, and the operation must be designed to suit the particular condition in the individual heart under consideration

Blood Pressure. Blood pressure should be taken four times daily and once at night, so that an average blood pressure level may be established.

Fluid Balance. Preoperative daily intake and output measurements when averaged form a sound base line for the amount of postoperative fluid to be administered.

Operative Care. The patient with coronary disease is usually apprehensive. For this reason, care should be taken to see that he is under deep sedation and is not taken to the operating room until the anesthetist is ready to start the anesthesia. Substernal pain prior to operation, when not relieved by nitroglycerin, may reflect a new occlusion with infarction and is a contraindication to surgery. Such patients should be returned to bed and watched for at least 1 week. The surgeon should ask the patient in the anesthesia room if he has precordial pain, if such pain is present, the operation should be postponed During the induction of anesthesia and the operation, the blood pressure must be maintained with Neosynephrine drip, which may be administered through a cut in the foot or arm. To avoid excess fluid, the Neosynephrine solution is strengthened as needed, starting with 5 ml Neosynephrine per 500 ml of 5 per cent glucose and water. It is advisable to insert a Wangensteen tube into the patient's stomach after induction of anesthesia to prevent gastric pressure on the heart postoperatively and to prevent paralytic ileus, which sometimes develops postoperatively.

Postoperative Care. The most important factor in postoperative care is to maintain the blood pressure at average preoperative levels Failure to do so favors cerebral and coronary thromboses.

Early ambulation is encouraged after certain types of operation, but after the internal mammary artery implant procedure, in which the pericardium is left open, movement is not permitted for 48 hr. After any coronary surgery, the patient has to live upon his own inadequate coronary circulation until extracardiac sources of blood can reach the myocardium. He should therefore be treated as though he had had a coronary artery occlusion with infarction, and should be given 4 to 6 months of convalescence to permit the new vessels to grow large enough to be of real value

Anticoagulant Therapy. The author and his coworkers have used anticoagulant therapy, by oral administration, starting on the second or third postoperative day. The value of this therapy in the treatment of coronary artery disease may be questioned, but it may be helpful in preventing thrombosis initiated by operation and bed rest.

RESULTS

The treatment of coronary artery disease is probably one of the most difficult to evaluate because of the numerous and unpredictable variations that occur during the natural course of the disease This is true for both medical and surgical therapy The comparison of individual cases is difficult, it is not so difficult, however, to compare groups of cases that fit into a certain broad classification. Such a basic classification has been established, and with excellent effect, for the surgery of mitral stenosis.

In the author's experience, there are two main groups of patients in which entirely dif-

ferent results may be expected from revascularization surgery. These are (1) patients with angina decubitus (i.e., pain at rest without exciting cause), and (2) patients with no pain at rest. Until objective radiologic evidence of improved myocardial circulation after surgery is available, the observer must rely upon the following criteria as indications of improvement: (1) survival, (2) disappearance of precordial pain for more than 6 months, (3) increase in work and exercise tolerance, (4) improvement in the ECG, and (5) failure to develop fresh infarction.

Survival. This pertains to both postoperative and long-term survival. The American College of Surgeons has defined the period of postoperative survival as the 30 days immediately after the operation. *Death during this period, no matter from what cause, must be recorded as a postoperative death.*

Dana and Ohler found a 7 per cent mortality of cardiac origin in patients who had suffered from pain at the time major surgery was performed. The same authors point out that there was no mortality of cardiac origin in patients with previous myocardial infarction who were asymptomatic at the time of major surgery, whereas the mortality was 40 per cent in a small group of patients who had had recent infarctions. Patients with coronary

tality above this figure fundamentally represents the true operative mortality for any given procedure.

Disappearance of Precordial Pain. Pain is subjective and thus very difficult to estimate both before and after operation. For this reason, the author's patients are seen by two cardiologists and a psychiatrist. Certainly, the disappearance of pain a few days or even a few weeks after surgical revascularization may be a psychologic phenomenon. The experience of the author's group indicates that *an attempt to evaluate the effect of an operative procedure should not be made less than 6 months after the operation.*

Increase in Work and Exercise Tolerance. In order to measure the improvement after operation, a careful record is made of the patient's ability to work and exercise before operation. Accurate questioning gives some indication of his ability as to exercise, e.g., the question, "How far can you walk in your town at the same pace as the crowd on the street?" invariably brings out that the patient may be able to walk a half-mile or so, but at a very reduced pace. The Master's two-step test and the treadmill, however, permit a much more dependable estimate of the patient's ability to exercise.

Improvement in the Electrocardiogram. The results obtained by electrocardiographic studies leave much to be desired. In the author's laboratory, the ECG has frequently failed to show evidence of improvement when the animal's exercise tolerance has returned to normal and when, later, autopsy findings have proved satisfactory myocardial vascularization. One should not place too much reliance on the ECG in estimating postoperative improvement or lack of it.

Failure to Develop Fresh Infarction. Revascularization surgery does not alter the predetermined course of coronary artery disease except to prevent myocardial fiber loss. Thus, coronary artery occlusion may and does sometimes occur after a revascularization procedure.

Evidence is now accumulating to indicate that *coronary artery occlusion may occur without evidence of myocardial infarction following a satisfactory revascularization.* This appears to have been true in at least five cases in which internal mammary artery implantation was performed.

There are three operations in use in the treatment of coronary artery disease in human beings which have had a most extensive experimental background and a long period of clinical trial. They are (1) the Beck I operation; (2) the internal mammary artery implantation (Vineberg); and (3) the Vineberg sponge operation.

The Beck I operation has a low over-all mortality; the good results are most impressive. Brofman reports 400 patients operated upon with an operative mortality of 5 per cent and a late mortality of 15 per cent. One hundred and ten of these patients were followed 3 to 5 years; the results were as follows:

Condition	*Percentage*
Excellent (little or no pain, working full time, no subsequent heart attacks)	39
Good (occasional heart symptoms, working more than before operation)	31
Fair (little apparent improvement)	6.4
Poor (no apparent benefit)	1.8
Died during operation	5
Died later	15
Total	98.2

It should be noted that of the 110 patients, 45 had severe precordial pain, 45 had moderate pain, and only 20 showed mild symptoms before opera-

Roentgenology. During the past few years, it has become possible to outline the coronary arterial tree. It is the author's opinion that in all patients being considered for surgical treatment of coronary artery insufficiency, the degree and location of occlusion of the coronary arterial tree should be outlined by one of the numerous techniques now available. RESULTS

The treatment of coronary artery disease is probably one of the most difficult to evaluate because of the numerous and unpredictable variations that occur during the natural course of the disease. This is true for both medical and surgical therapy The comparison of individual cases is difficult; it is not so difficult, however, to compare groups of cases that fit into a certain broad classification. Such a basic classification has been established, and with excellent effect, for the surgery of mitral stenosis

In the author's experience, there are two main groups of patients in which entirely dif-

it to a femoral artery. Two of the 3 patients survived the procedure, 1 of them died 10 days later from a fresh coronary artery occlusion and infarction

There is considerable disagreement at present as to the best means of bringing about circulatory assistance in cases of coronary artery shock. Some subscribe to the principle outlined by Dennis and his group, who indicated that a good result can be obtained by using the pump-oxygenator Others feel that this technique hinders rather than helps the failing heart; this opinion, however, has been based on experience in the experimental laboratory, which is not comparable with experience in human beings, where there is failing circulation because of a failing left ventricle.

Some investigators have suggested that circulatory assistance in coronary artery shock be provided by passing a catheter through the superior vena cava into the left atrium through the interatrial septum, thus withdrawing the blood from the left atrium and passing it into a heart-lung machine and back into a femoral artery. *Left heart bypass* is suggested to relieve the left heart of any strain. This procedure has been carried out, to the author's knowledge, in one patient in Sweden, but unfortunately the patient died. The future of circulatory assistance in coronary shock is certain to be great.

tion. The patients who died later had an average preoperative duration of symptoms of 4 years. Forty per cent of the patients had two or more episodes of acute myocardial infarction before operation Brofman reports that 20 per cent of the patients had left ventricular enlargement but only a few had evidence of any congestive failure.

Hill has surveyed the results of the first consecutive 36 patients who underwent internal mammary artery implantation at the Royal Victoria Hospital Figures have been compiled by Hill on the basis of a 5- to 9-year follow-up. The operative mortality for this group was 13 per cent, on the basis of the author's experience, 4 of the 5 patients who died in this series would not be operated upon today. The 5- to 9-year study of the 31 patients who survived the operation showed marked improvement in 67 7 per cent of them. In this group, 7 per cent had complete pain relief within the first 9 months As time passed, an increasing number of patients became pain-free, until at the end of 3 years 37 per cent of the group were completely free of pain. Some 75 per cent of these patients had been disabled before surgery, 72 per cent returned to work after surgery *The combined Vineberg and Walker series of 110 patients with coronary artery disease treated by internal mammary artery implantation showed that the over-all mortality rate for the two series for patients who had had no pain at rest was 5 8 per cent.*

In the group of 110 patients in which there was no precordial pain at rest, 72 per cent were totally disabled prior to operation. Most of the patients could walk approximately one-half a city block prior to operation. After the operation, over 78 per cent had no pain or had less pain, and 79 per cent returned to work.

The Vineberg Sponge. This operation has been used in the past 3 years with considerable success in the treatment of patients over 60 years of age, those with ventricular hypertrophy and those with chronic left and right ventricular failure. The internal mammary artery implantation and the Beck I operation have been reserved for patients with no precordial pain at rest without exciting cause and with small left ventricles.

Patients with chronic ventricular failure who had been digitalized and "dried up" before operation, in general withstood surgery quite well, the operative mortality for a group of 24 patients was less than 8 per cent In the entire group, 22 individuals had had previous infarction and 21 had chronic ventricular failure (right, left, or both). Twenty-nine patients were suffering from precordial pain, and 19 were unable to work. Following surgery, 15 patients were pain-free and 18 improved markedly.

SURGERY OF LESIONS OF THE HEART RESULTING FROM CORONARY ARTERY INSUFFICIENCY

In the operating room, the author has encountered two unsuspected cases of *right ventricular aneurysm*. Both cases were treated by the Ivalon sponge procedure. There are, however, in the literature, reports of *left ventricular aneurysms* that have been successfully treated using extracorporeal circulation, by resection of the aneurysm and resuturing of the cut surfaces of the left ventricle.

When the aneurysm is saccular, the incision is small, when the aneurysm is large and fusiform, a very large portion of the ventricle has to be resected and usually a considerable quantity of intraventricular thrombus must be removed Usually patients with this condition come to the attention of the surgeon following two to three previous infarctions and because of left ventricular failure Recently, the author resected a left ventricular aneurysm which involved the entire anterior surface and a good part of the lateral surface of the left ventricle The incision measured over 20 cm in length The patient was in chronic left ventricular failure following three myocardial infarctions The aneurysm extended out to the chest wall in the midaxillary line. Resection was carried out without difficulty, using extracorporeal circulation, and the patient had an uneventful postoperative convalescence

The *ruptured intraventricular* septum following myocardial infarction has likewise been repaired with success in a few instances using extracorporeal circulation. Some of the patients have died later from another attack of myocardial infarction, but at autopsy, the repaired intraventricular septum has been shown to be unchanged.

Ruptured papillary muscles usually occur because of rupture of a lateral papillary muscle which results in mitral insufficiency. A few patients with this condition have been operated upon, and the mitral insufficiency has been di-

The surgery of ventricular aneurysms

HOUCK E. BOLTON AND CHARLES P. BAILEY

An aneurysm of the ventricle of the heart may be defined as a more or less localized outpouching of the continuity of the wall of the ventricular chamber. Such aneurysms may be the result of a congenital malformation (so-called diverticulum), accidental or surgical trauma, or degenerative changes in the muscle fibers (postinfarctional).

The first recorded case of ventricular aneurysm was reported by Hunter (1757). The first operative attack upon such a lesion was made inadvertently by Sauerbruch (1937). While attempting to remove a mediastinal tumor, he made a limited incision into such an aneurysmal sac, allowing palpation of the interior of the ventricular chamber. This cardiotomy incision was closed by simple suturing of the opening.

Deliberate suture plication and constriction of the base of an aneurysm sac in order to decrease the size of the lesion was described by Beck (1944). More recently, D'Allaines reported a case in which a similar principle was employed. Actual resection of a ventricular aneurysm was first attempted by Glover (1953). Using a somewhat different technique, Bailey (1954) performed a subtotal resection of a postinfarctional type aneurysm with survival. Since that time, eight additional patients have been treated similarly with but one death.

ETIOLOGY

The development of a *diverticulum of the ventricle* is believed by Drennan and Van de ... s of ... The ... any unusual increase in intraventricular pressure occur during prenatal development.

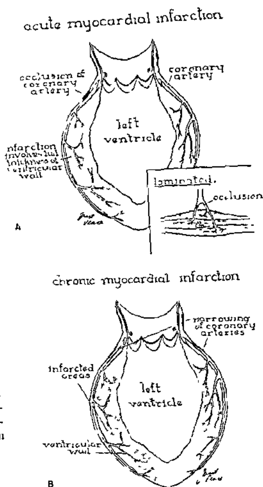

Fig. 10-27 A. Acute myocardial infarction involving full thickness of ventricular wall is shown in comparison to the laminated type of acute myocardial infarction which involves a layer of muscle in the myocardial wall. B. Chronic myocardial infarction demonstrating spotty irregular areas of myocardial fiber death and replacement by scar tissue.

tion and, to a degree, impedes filling from the left atrium—similar to the dysfunction associated with aortic regurgitation

DIAGNOSIS

Patient Selection. The symptoms, signs, and electrocardiographic changes associated with ventricular aneurysms may provide only a suspicion of its presence. An abnormal bulge in the x-ray silhouette and a paradoxically pulsating mass seen along the heart border by fluoroscopic examination are observed in most cases (Fig 10-28A) Those patients having an actual paradoxic movement of the wall or having signs of chronic heart failure following a history of myocardial infarction should be studied by roentgen- or electrokymography or, preferably, by opacification of the ventricular chamber. Such opacification by a contrast medium, such as 70 per cent Diodrast or 90 per cent Hypaque, is now done by direct ventricular puncture in preference to left atrial injection. Serial radiographs demonstrate the changes in size with systole and diastole and confirm the site of origin from the ventricular chamber (Fig. 10-28B, C).

Nonvisualization of the lumen of an attached aneurysm by such a method of examination may suggest that the sac contains soft thrombotic material. Paradoxic motion is not observed in these cases. Anticoagulant therapy to preclude embolization may be used in such a case in preference to surgical methods. If treated medically, anticoagulant therapy

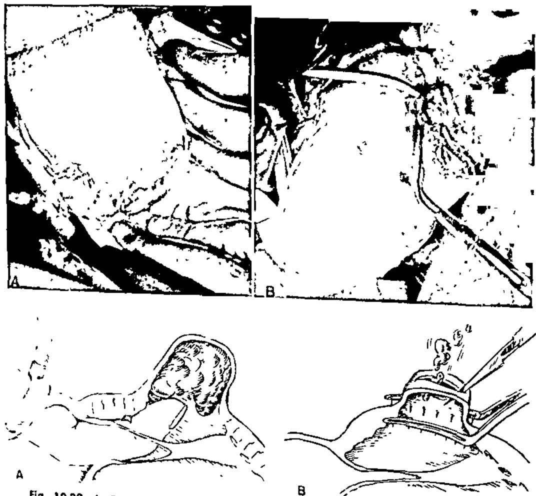

Fig 10-29. A Diagram demonstrates digital exploration of the aneurysm through the appendage and mitral valve The photograph shows the intact aneurysm. B. The diagram shows the method of "flushing out" contained thrombi, prior to closing the clamp. The photograph shows the clamp applied to the base of the aneurysm.

Posttraumatic aneurysms will undoubtedly become more common. The advent of cardiac surgery has introduced the necessity of many ventriculotomies, and one must assume that a very small percentage of such procedures will be followed by a weakened area of the myocardium. Other types of accidental injuries likewise provide a possible source of aneurysmal lesions.

The most common cause of ventricular aneurysm is the myomalacia which follows *acute coronary arterial occlusion*. On the basis of Master's estimated incidence of myocardial infarction, it is believed that between 25,000 and 200,000 new cases of ventricular aneurysm develop annually in the United States alone. These aneurysms, unfortunately, are frequently overlooked.

PATHOPHYSIOLOGY

As the entire thickness of the myocardium is involved in large infarcts, most of the muscle fibers are destroyed and undergo liquefaction necrosis The central portion of the infarct heals much more slowly than does the periphery. Should undue strain be placed upon this area during the healing phase, the thin central portion may bulge outward into a noncontractile paradoxically expansile pouch Since the aneurysm develops initially from a large area of myomalacia, it becomes sessile with no true neck. The overlying pericardium becomes adherent and markedly thickened, thereby preventing rupture after the initial healing has begun.

An aneurysm exerts an extremely deleterious effect upon the ability of the ventricle to maintain an adequate net stroke output. Because of its semielastic nature, the wall of the sac stretches during systolic contraction of the ventricle, producing a paradoxic pulsation during systole. The dysfunction produced is similar to that present in mitral regurgitation. A certain portion of the ventricular content is wasted since it is not expelled into the aorta During diastole, the sac collapses, emptying its contained blood into the chamber of the ventricle This produces left ventricular dilata-

Fig. 10-28. A. Posteroanterior and lateral roentgenogram in a 42-year-old white male showing a true ventricular aneurysm with a small neck. B Contrast visualization by direct injection of 70 per cent Diodrast into the left ventricle C. Postoperative contrast visualization roentgenogram showing an essentially normal cardiac chamber.

tained thrombi is provided by wide incision of the aneurysm. Hemostasis is restored promptly by the application of a special clamp designed to prevent slippage from the neck of the sac (Fig. 10-29B). Postoperative embolization may be prevented by anticoagulant therapy.

SURGICAL TECHNIQUE

Although Beck advocated reduction in size of these aneurysms by reenforcement with fascia lata, this type of procedure would seem to be inadequate and perhaps hazardous in the presence of intraluminal thrombosis. Complete excision of the sac, as undertaken by a number of surgeons, has been followed by a fatal outcome in some cases These deaths have been attributed to embolic episodes or to the persistence of intractable heart failure following the surgery. Experimental work suggests that reduction in the diastolic capacity of the underlying ventricular chamber may precipitate chronic heart failure The type of circulatory obstruction produced by ventricular resection in dogs appears similar, functionally, to that which is observed in experimentally produced mitral stenosis. Postoperative compensatory dilatation of the ventricle was not observed in the authors' experience

The currently employed method of ventriculoplasty avoids both the threat of embolic episodes and the chronic heart failure because of a wide resection with reduction in left ventricular filling capacity The aneurysmal sac is "tailored," so that expansion is prevented and so that the heart is changed to one of optimum shape and efficiency. The thin apical portion of the sac is resected, while the strong basal portion is utilized to construct a secure fibrous wall of the ventricle (Fig 10-30) If a papillary muscle takes origin from the wall of the sac, it may be included in the clamp and suture line The normal valvular supports will remain unchanged, and mitral incompetence will not be created

A special multitoothed clamp is applied across the base of the sac immediately after the fundus of the aneurysm is opened. This allows the intraventricular pressure to eject any thrombotic material before the clamp is closed completely. This precaution has seemed to prevent systemic embolization.

TABLE 10-2. RESULTS OF OPERATION

Type of aneurysm	*No of cases*	*No. of deaths*	*Cause of death*
Congenital	1	0	0
Posttraumatic	2	0	0
Degenerative	6	1	Systemic embolization

The surgical problem is significantly altered in false aneurysms following trauma or surgical incisions The actual size of the left ventricular chamber may remain unaltered, and the ventricle most frequently communicates with the aneurysm through a small fistula. Excision of the sac with suture repair of the communicating opening has provided a permanent correction.

The results of excision in congenital diverticula have been excellent The cases discussed include one such patient. Excision was accomplished by clamping the base of the sac and by simple suture. However, in the treatment of the postinfarctional aneurysm, results have been generally less satisfactory. Using the tailoring principle of ventriculoplasty, five patients have survived The death reported in this group was due to dislodgment of an attached mural thrombus with systemic arterial embolization This accident may be avoided by the "flush-out" technique as described above. The remaining patients in this group have attained an excellent postoperative result, with the exception of one patient who developed a second aneurysm.

The posttraumatic aneurysms encountered followed previous heart surgery One of them occurred through the weakened cicatrix at the site of a ventricular tear produced during mitral commissurotomy The other occurred through a ventricular scar due to transventricular aortic commissurotomy These aneurysms were treated by simple suture of the defect in the ventricular wall, with a good postoperative result in each case.

should be planned for the patient's entire life span, or until such a time when the aneurysm and its contained clot may be eradicated.

Since most of these patients present a history of one or more myocardial infarctions, it must be assumed that some degree of damage exists even in the remaining "normally functioning" myocardium. These patients are poor surgical risks. Surgical intervention should be deferred until 6 months after the last coronary occlusion. This period of healing will provide adequate time in which dense scarring may be formed about the neck of the aneurysmal sac. Excision should be recommended only when paradoxic motion can be demonstrated by kymography, fluoroscopy, or ventricular opacification. This is substantiated by a review of postmortem studies of aneurysms. Rupture of a postinfarctional aneurysm seldom occurs. The mechanism producing death is usually congestive failure—related to the mechanical inefficiency produced by the presence of the semielastic sac. More infrequently, contained thrombotic material may become detached and result in peripheral embolization.

During the surgical procedure, certain steps are essential to prevent systemic embolization. Intracardiac exploration by way of the left auricle and the mitral valve provides an accurate method for the recognition of mural thrombi about the neck of the sac (Fig. 10-29A). Complete external flushing of con-

PART II

Disturbances of the heart rate and rhythm; excitability and conduction disturbances

PART II

Disturbances of the heart rate and rhythm; excitability and conduction disturbances

1

Disturbances due to modified function of the sinoatrial node

ALDO A. LUISADA

SINUS TACHYCARDIA

Cause and Types. The most common sinus tachycardia is caused by *exercise*. It lasts for a long time if the heart muscle is weak.

Digestion is often accompanied by increased heart rate. This occurs if the quantity of food and drink is too great or if the heart muscle is weak. The ingested fluid increases the volume of circulating blood, thus increasing cardiac strain.

Assuming the erect position is accompanied by an increased heart rate because of decreased intensity of carotid sinus reflexes. *Emotion* is accompanied by tachycardia. Many *drugs* and *poisons* also cause tachycardia. Among them, caffeine and nicotine are the most commonly used. *Fever* is usually accompanied by rapid heart action.

Endocrine disorders may be accompanied by rapid heart, the most frequent such cause being hyperthyroidism.

Valvular defects, pericardial lesions, and *high or low blood pressure* may be accompanied by sinus tachycardia, because they either increase the work of the heart and, therefore, are the equivalent of exertion, or cause reflex acceleration of the heart beat through changes of stretch of vascular receptors.

If the *myocardium is weak*, the heart maintains its output by reducing systolic discharge and increasing its rate.

Sympathetic irritation or a *lesion of the vagus nerve* may be responsible for a rapid pulse.

Signs and Symptoms. The patient usually does not feel the tachycardia, but if it is too high, he may complain of *palpitation*.

The pulse is regular and often small. It has no fixed rate; therefore, exercise, change of position, and respiration may vary it. Spontaneous variations are also common. The heart *sounds* are regular and frequently have equal duration and loudness.

Graphic Methods. ELECTROCARDIOGRAM. The atrial and ventricular waves follow each other in a normal way (Fig. 11-1A). The P-R interval may be slightly longer than normal but is not over 0.20 sec. Diastole is short, so that the end of the T wave is near the following P wave. In the adult, the rate varies between 90 and 150 but is seldom above 100. Occasionally, higher figures have been described.

JUGULAR TRACING. There may be fusion of the *V* wave with the following *A* wave.

PHONOCARDIOGRAM. The heart sounds are short and loud. A triple rhythm is not unusual because of tumultuous ventricular filling.

Diagnosis. Sinus tachycardia can usually be recognized because (1) it is connected with a definite cause; (2) it does not start suddenly; (3) it is well tolerated; (4) very seldom does the rate exceed 150; (5) the rate frequently changes; and (6) there is a normal electrocardiogram.

Paroxysmal tachycardia gives an abnormal electrocardiogram, starts suddenly, and is less well tolerated.

Treatment. Treatment is directed, whenever possible, to removal of the cause. Whenever high excitability of the sympathetic system is involved, *ergotamine* or *Hydergine* may be used.

Digitalis or *quinidine* is indicated in some cases. *Coramine* may be used with low blood pressure.

Rest, sedatives, and treatment of the thyroid condition are necessary in some cases. In particularly severe and intractable cases, removal of the upper thoracic sympathetic ganglia (second to fifth) may be necessary.

SINUS BRADYCARDIA

Cause and Mechanism. Sinus bradycardia may result from *poisoning* or *infection*. Poisoning from biliary salts (jaundice) or products of metabolism (uremia) is not uncommon Poisonous mushrooms, morphine, and digitalis cause bradycardia. Typhoid, diphtheria, rheumatic disease, mumps, pneumonia, and cholera may cause relative or absolute sinus bradycardia. In particular, rheumatic carditis causes bradycardia in about 10 per cent of the cases.

Convalescence is frequently accompanied by a slow pulse due to sinus bradycardia.

Increased intracranial pressure is revealed by a slow pulse *Visceral colicky pain* also is usually accompanied by slow pulse.

Patients with *myocardial fibrosis* may have a persistently slow pulse which is only slightly affected by the position of the patient.

Hypothyroidism is frequently associated with bradycardia, which may even reach the low rate of 40 per minute.

Patients with *abnormal sensitivity of the carotid sinus* have a sudden slowing of the pulse when a change of position or an external compression stimulates the carotid receptors.

Lastly, some *normal individuals* have a constantly slow pulse, their condition has been called *vagotonia*. *Athletes* frequently have a slow pulse.

In all these cases, three possible mechanisms may exist. (1) a continuous reflex action slows down the heart by way of the vagus nerve, (2) there is a high tonus and excitability of the medullary center of the vagus, so that normal stimuli are sufficient for maintaining the slow pulse; (3) the SA node itself is affected.

The reflex mechanism is involved in the cases with visceral pain or hypersensitive carotid sinus and may be involved in cases of myocarditis. A high excitability of the vagus occurs in patients with high intracranial pressure, in hypothyroidism, in drug action, and in normal individuals with slow pulse. Direct change of the function of the SA node is involved in myocardial fibrosis, in severe myocarditis, and also in cases of poisoning. However, in many cases, a double mechanism (action on the

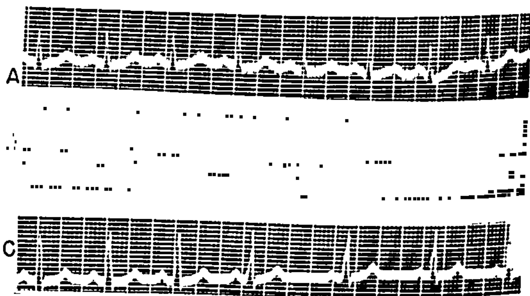

Fig. 11-1. Modifications of the heart rate and rhythm due to the SA node and revealed by the ECG. A. Sinus tachycardia. B. Sinus bradycardia. C. Sinus arrhythmia.

cardiac muscle and on the vagus nerves) is involved. This is also true for digitalis.

A paralysis of the accelerator nerve is possible in some cases, as a result of a central or peripheral lesion, but this is the least frequent mechanism.

Signs and Symptoms. Symptoms are usually absent, but a *further strong stimulation* of the vagus (sudden immersion in cold water, emotion, or pain) may cause *fainting* In such a case, a vascular collapse is frequently associated with the bradycardia.

The pulse is slow and regular but may present marked respiratory arrhythmia. The heart sounds and the pulsations of the jugular veins are normal

The *systolic blood pressure* may be normal or slightly low and is usually accompanied by a large pulse pressure

Graphic Methods. ELECTROCARDIOGRAM. The electrocardiogram is normal and shows a long diastole The P-R interval is normal. The rate is usually between 65 and 50, and only exceptionally between 50 and 40 (Fig. 11-1B)

PHARMACOLOGIC AND FUNCTIONAL TESTS The most important is the *atropine test*. Injection of 1 mg atropine sulfate hinders the action of the vagus nerve and accelerates the heart rate Another pharmacologic test involves the *inhalation of amyl nitrite* This is particularly effective in patients with coronary heart disease and bradycardia caused by functional depression of the SA node

Changes of position, exertion, and deep *respiration* are usually sufficient to accelerate the pulse in persons with sinus bradycardia Compression of the *carotid sinus* may arrest the heart in patients with bradycardia *due to* hypersensitive carotid receptors Both this maneuver and compression of the eyeballs may also arrest the heart in patients with an excitable *vagus nerve*

Diagnosis. Diagnosis is not difficult in most of the cases Clinical data are *usually sufficient* and may be supplemented by the *functional* and pharmacologic tests The electrocardiogram may be needed in doubtful cases or when the rate is very slow

Differential diagnosis should be made from *nodal rhythm, type 2:1 AV or SA block*, and complete AV block In the latter, there *is* usually a slower pulse, but patients with congenital AV block may have a pulse between [illegible]

Treatment. No treatment is required in most cases. If possible, the cause of the bradycardia should be removed.

In some cases, *atropine, ephedrine, Benzedrine, caffeine,* or *nitrites* will be required. Nitrites are useful *only* in patients *with coronary* heart disease

SINUS ARRHYTHMIA

Cause. This common irregularity of the pulse is usually associated with respiration. It is particularly evident in children, convalescents, or persons with unusually high excitability of the vagus nerve. It is also frequently present when *pleuropericardial adhesions* are *stretched by respiratory movements.* It may occur in old people with arteriosclerotic lesions and coronary heart disease, and in children with rheumatic carditis.

Signs. The pulse is periodically and alternately rapid and slow Slowing down of the pulse may be abrupt *but is usually gradual* in onset. The pulse may seem intermittent in the first case *These changes* of the heart rate are connected with respiration, *the phase of* rapid pulse occurring in the second half of inspiration and that of slow pulse in the second half of expiration

Deep breathing accentuates the phenomenon, *suspension of respiration* causes its disappearance. *Atropine* usually abolishes sinus arrhythmia

Graphic Tracings. ELECTROCARDIOGRAM. The electrocardiogram has normal waves, it shows, in general, gradual changes in the length of diastole (Fig. 11-1C). If there are sudden changes and the long diastole is equal to twice *the* P-P *interval*, the cause is SA block.

ARTERIAL TRACING The pulse waves become gradually larger and have a lower starting point, then become smaller *again*, with a higher starting point. This indicates *higher* systolic and lower diastolic pressures during the phase of slower pulse, usually during the *second half of expiration*

Mechanism. The various mechanisms of sinus arrhythmia are *illustrated* by the following scheme.

SINUS ARRHYTHMIA

Vagal:	Myocardial:
Respiratory	Incomplete SA block
Hypoxic (bulbar)	Type I *(periodic)*
Independent	Type II (intermittent)
	SA standstill

Diagnosis. The diagnosis can be made by means of the simple tests already described. Suspension of respiration causes a disappearance of the phenomenon. Atropine can be used in doubtful cases.

Differential diagnosis should be made with SA block. *Periodic SA block* may be connected with respiration and may be affected in the manner of respiratory arrhythmia by the functional tests. However, in SA block, *the long pause is equal to twice the short one;* in respiratory arrhythmia, the long pause is *less than double;* the increase is gradual in the latter.

Prognosis and Treatment. Prognosis is favorable except in those cases where the irregularity reveals an initial cardiac failure (coronary heart disease or acute rheumatic carditis. Therefore, correlation between sinus arrhythmia and all other clinical data is necessary.

No treatment is necessary. Atropine may cause disappearance of the disturbance.

2

Paroxysmal tachycardia

MAX HOLZMANN

Paroxysmal tachycardia is the name given to paroxysmal episodes of rapid heart action with sudden beginning and sudden end. Thus, the term is used in both a general and a limited sense, depending upon whether *acute episodes of atrial fibrillation* and flutter are included or not. The classification below gives an over-all picture of the various groups as revealed by the electrocardiograph.

HISTORICAL INTRODUCTION

According to Willius and Dry, Williams (1835) first described a case of paroxysmal tachycardia. Payne-Cotten (1667) published a typical case observation. A penetrating analysis of the disease was given by Bristowe (1888), and Bouveret (1889) separated out the paroxysmal rhythmic types from the numerous other forms of tachycardia, and coined the term used at present. Finally, Hoffmann (1900) published a well-known monograph on this syndrome.

With the help of the electrocardiogram, it was possible to separate paroxysmal tachycardia from paroxysmal atrial fibrillation or flutter. The discovery of the ventricular tachycardias was due to the use of the electrocardiograph. As a result, T. Lewis (1909) was able to describe short episodes of ventricular tachycardia in a patient and to produce ventricular tachycardia in a dog by means of coronary artery ligation. Robinson and Hermann (1921) demonstrated that, in man also, ventricular tachycardia can be caused by occlusion of a coronary artery.

DIFFERENTIATION OF THE PAROXYSMAL TACHYCARDIAS

The classification of the entire entity is based partly on clinical findings and partly on the electrocardiographic picture.

CLASSIFICATION OF PAROXYSMAL TACHYCARDIAS

Paroxysmal tachycardia *in a strict sense*.
- Essential paroxysmal tachycardia (Bouveret-Hoffmann type).
  - Supraventricular:
    - Rapid
      - With AV block
      - Without AV block
    - Moderate
  - Ventricular
    - *Rapid*
    - Moderate
- Extrasystolic paroxysmal tachycardia (Gallavardin type)
  - Supraventricular
  - Ventricular

Paroxysmal atrial flutter
Paroxysmal atrial fibrillation

Clinically, the classical form of paroxysmal tachycardia is revealed by the sudden occurrence of a regular and rapid heart action at 150 to 220 beats per minute (occasionally higher rates were encountered). In adults, the rate is usually below 200, while in infants and small children, it can exceed 300. In addition to the *rapid form of paroxysmal tachycardia*, a less common, *moderate form* can be observed, with a rate of 120 to 135 per minute. The uncomplicated cases are generally typical on account of the remarkable regularity of the rhythm. Two different entities can be separated clinically but without sharp differentiation:

1. The classical *paroxysmal tachycardia* (*Bouveret-Hoffmann type*). It is characterized by the sudden and unexpected onset of a regular tachycardia and by an equally sudden ending, while between *attacks, the heart* action is slow and regular or presents, at most, occasional premature beats.

Diagnosis. The diagnosis can be made by means of the simple tests already described. Suspension of respiration causes a disappearance of the phenomenon. Atropine can be used in doubtful cases.

Differential diagnosis should be made with SA block *Periodic SA block* may be connected with respiration and may be affected in the manner of respiratory arrhythmia by the functional tests. However, in SA block, *the long pause is equal to twice the short one,* in respiratory arrhythmia, the long pause is *less than double,* the increase is gradual in the latter

Prognosis and Treatment. Prognosis is favorable except in those cases where the irregularity reveals an initial cardiac failure (coronary heart disease or acute rheumatic carditis. Therefore, correlation between sinus arrhythmia and all other clinical data is necessary.

No treatment is necessary. Atropine may cause disappearance of the disturbance.

ble that they are also instigated in a similar fashion. In general, there seems to be a great variety of favoring elements. Physical exertion, certain body positions, gastrointestinal distention, constipation, pain in remote parts of the body, or emotion are the most common triggers. A relationship to body position is occasionally demonstrated In an unusual case described by Fine and Miller, atrial tachycardia began while the patient was in the erect position, had a higher rate while he was standing, a more moderate one while he was sitting, and was even less rapid when the patient was lying down, until it finally disappeared

SYMPTOMS The onset of the tachycardia is often recognized by the patient through an awareness of the heart Most patients feel a slight *pressure* on the chest, often a slight degree of *dyspnea* If cardiac dynamics are increased because of associated disease (hyperthyroidism, aortic insufficiency), the rapid pulsations become powerful On the other hand, the rapid rate can be completely unknown to the patient The author discovered paroxysmal tachycardia at a rate of 200 in an ambulatory patient with aortic insufficiency, the patient had no idea of its presence Wenckebach and Winterberg reported a case of a woman who consulted her physician only because she was disturbed, while in company, by visible pulsations of her neck vessels

The rapid heart activity can be felt as palpitation of the precordium or as pulsations in the neck or head Nausea, sweating, tinnitus, and faintness may occur The attack may be associated with an urge to urinate Less frequently, palpitation is associated with *precordial pain* If it is of slight degree, the latter is not alarming However, if it is severe, the presence of coronary sclerosis must be considered Sometimes, there is a "status anginosus," which persists as long as the tachycardia. Under these conditions, the persistence of precordial pain, even for several hours, should not be accepted as evidence of an infarct If the pain still persists *after* the termination of the tachycardia, on the other hand, an infarct has probably occurred Occasionally, the end of the attack is particularly unpleasant. A *lightning-like pain* in the *cardiac region*, often with radiation to the left arm, or *vertigo*, or even loss *of consciousness* may terminate the [illegible] [illegible]e latter may be due to *cardiac arrest* lasting several seconds. Most often the patients cannot describe the end of the attack because *it is followed* by sinus tachycardia. After the attack, many patients feel tired and weak for hours; others, on the contrary, are immediately able to resume their activities.

OBJECTIVE FINDINGS During an attack of tachycardia, the examining physician should count the rate during auscultation of the heart, because the pulse count is often misleading. The *radial pulse* may be small and weak, may vary in fullness with respiration, may alternate, and may be uncountable or even imperceptible. Occasionally, *pulsus alternans* can be demonstrated by a sphygmomanometer (or a pulse tracing) even though palpation fails to reveal it.

Often, strong pulsations of the *jugular veins* are present. Wenckebach (1910) first recognized this phenomenon in the phlebogram and stated that it was caused by summation waves due to superposition of the A and C waves of the venous pulse. If the attack ended, the pulsations also disappeared. *Auscultation* of the heart is characterized by a similar duration of the interval between the two heart sounds, designated by Huchard as *embryocardia* In other cases, the 1st heart sound is much louder than the 2d, in fact, the latter may be imperceptible Then, the danger of counting only one-half the beats must be avoided Previously existing murmurs may disappear during the tachycardia, or a *rough systolic murmur* may be added. A final evaluation of the auscultatory findings of the heart, and the conclusions drawn from them, must therefore be delayed until the attack is over.

The evaluation of *heart size* is today based on *x-ray* findings, which can be interpreted correctly only through comparison with films taken between attacks In uncomplicated cases, it can be demonstrated that the heart becomes *smaller* during the attack, which is what one would basically expect since diastole is relatively more shortened than systole (Dietlen; Groedel, Vaquez and Bordet). This is especially noticeable during a prolonged attack, and then atrial dilatation occurs as a result of venous engorgement and ineffective atrial contractions, a fact which is particularly true for the right atrium. After termination of the attack, a return of the right atrium to normal size can be noted, although the size of the

2. *Paroxysmal extrasystolic tachycardia (Gallavardin type)*. Runs of tachycardia follow each other for various periods of time, while in the intervals, there are single or short series of extrasystoles. In this way, palpation of the pulse may give the impression of an arrhythmia. Among the subgroups described by Gallavardin, three deserve special mention:

a. *The excitable form of paroxysmal tachycardia ("tachycardie à centre excitable")*, in which the attacks are not completely without cause and are easily provoked by slight physical strain or psychic excitement. Sometimes, as a result, there are extremely numerous attacks, most of them brief. However, the heart does not return to a normal rhythm in the intervals because of the frequent premature beats. The extraordinary lability of this condition constitutes a serious drawback for the patient.
b. *The prolonged form of extrasystolic paroxysmal tachycardia ("extrasystolie à paroxysmes tachycardiques")* or "repetitive paroxysmal tachycardia" of Parkinson and Papp, which is distinguished by its persistence over long periods of time (even many years) with only short interruptions of extrasystoles. This form has no apparent cause.
c. *The terminal extrasystolic tachycardia* occurs in patients with advanced coronary insufficiency and represents a prefibrillatory stage of severe prognosis.

The *ECG* makes it possible to divide the various forms of paroxysmal tachycardia *according to their origin* into *supraventricular* and *ventricular*. It also permits one to evaluate irregularities of rhythm, if they occur. This differentiation is of particular interest for therapy.

The pulse rate permits a presumptive differential diagnosis, but whenever possible, it should be confirmed by electrocardiography. The distinguishing features of the various types can be described as follows.

In *essential paroxysmal tachycardia (Bouveret-Hoffmann type)*, the attack may last from a few seconds to several days. It is followed by completely normal rhythm. During the attack, there is a regular rhythm with a rate of from 120 to 220 beats per minute in adults, and often over 300 in small children. The typical attack of palpitation usually is in the range of 165 to 200 in the adult.

In *extrasystolic tachycardia (Gallavardin type)*, there are occasional short runs of extrasystoles, and the attacks can follow each other with short pauses for a long period of time. The rate is somewhat lower, ranging from 125 to 190, and the rhythm is often not so regular as in the previous type.

The ventricular form of tachycardia may be transformed into dangerous attacks of *ventricular flutter* (regular rate over 300) or *ventricular fibrillation* (irregular rhythm).

The regular forms of atrial flutter are associated with a much more narrowly limited ventricular rate, which with a 1:1 conduction lies at 195 to 220, and with a 2:1 conduction, at 130 to 150. Therefore, a differentiation is often possible.

The *frequency range of the tachyarrhythmias* is in contrast very large, and stretches from an upper limit of about 215 down to the normal range, in which it loses its paroxysmal aspects. This range is determined mainly by the variable AV conduction in *atrial fibrillation, atrial flutter*, and *extrasystolic tachycardia*.

SUPRAVENTRICULAR TACHYCARDIA

Under this designation are grouped all paroxysmal types which have their origin in the region of the atrium or in the AV node. These, in turn, should be divided into *sinus, atrial*, and *nodal* tachycardia. The occurrence of paroxysmal sinus tachycardia has not been demonstrated. According to the view of most of the current authors (Scherf and Schott, 1953, Bellet, and others), nodal (AV) tachycardia is rare. *Supraventricular tachycardia is usually caused by an atrial ectopic focus.* For this reason, these forms are often grouped together under the name of "atrial" tachycardia. The term chosen here, however, is preferable because it includes all the possible forms.

The Clinical Picture. In general, the patient with a typical form of paroxysmal tachycardia experiences an attack in a completely unexpected manner. He is usually in a normal state of health and may be asleep. Exceptionally there is a *premonitory warning*, usually a general feeling of malaise hours or days before

ble that they are also instigated in a similar fashion. In general, there seems to be a great variety of favoring elements Physical exertion, certain body positions, gastrointestinal distention, constipation, pain in remote parts of the body, or emotion are the most common triggers. A relationship to body position is occasionally demonstrated In an unusual case described by Fine and Miller, atrial tachycardia began while the patient was in the erect position, had a higher rate while he was standing, a more moderate one while he was sitting, and was even less rapid when the patient was lying down, until it finally disappeared

SYMPTOMS The onset of the tachycardia is often recognized by the patient through an awareness of the heart Most patients feel a slight *pressure* on the chest, often a slight degree of *dyspnea* If cardiac dynamics are increased because of associated disease (hyperthyroidism, aortic insufficiency), the rapid pulsations become powerful On the other hand, the rapid rate can be completely unknown to the patient The author discovered paroxysmal tachycardia at a rate of 200 in an ambulatory patient with aortic insufficiency, the patient had no idea of its presence. Wenckebach and Winterberg reported a case of a woman who consulted her physician only because she was disturbed, while in company, by visible pulsations of her neck vessels

The rapid heart activity can be felt as palpitation of the precordium or as pulsations in the neck or head Nausea, sweating, tinnitus, and faintness may occur The attack may be associated with an urge to urinate Less frequently, palpitation is associated with *precordial pain* If it is of slight degree, the latter is not alarming However, if it is severe, the presence of coronary sclerosis must be considered Sometimes, there is a "status anginosus," which persists as long as the tachycardia Under these conditions, the persistence of precordial pain, even for several hours, should not be accepted as evidence of an infarct If the pain still persists *after* the termination of the tachycardia, on the other hand, an infarct has probably occurred Occasionally, the end of the attack is particularly unpleasant A *lightning-like pain* in the *cardiac region*, often with radiation to the left arm, or *vertigo*, or even *loss of consciousness* may terminate the attack. The latter may be due to *cardiac arrest* lasting several seconds. Most often the patients cannot describe the end of the attack because it is followed by sinus tachycardia. After the attack, many patients feel tired and weak for hours, others, on the contrary, are immediately able to resume their activities.

OBJECTIVE FINDINGS During an attack of tachycardia, the examining physician should count the rate during auscultation of the heart, because the pulse count is often misleading The *radial pulse* may be small and weak, may vary in fullness with respiration, may alternate, and may be uncountable or even imperceptible. Occasionally, *pulsus alternans* can be demonstrated by a sphygmomanometer (or a pulse tracing) even though palpation fails to reveal it.

Often, strong pulsations of the *jugular veins* are present. Wenckebach (1910) first recognized this phenomenon in the phlebogram and stated that it was caused by summation waves due to superposition of the A and C waves of the venous pulse If the attack ended, the pulsations also disappeared *Auscultation* of the heart is characterized by a similar duration of the interval between the two heart sounds, designated by Huchard as *embryocardia.* In other cases, the 1st heart sound is much louder than the 2d, in fact, the latter may be imperceptible Then, the danger of counting only one-half the beats must be avoided Previously existing murmurs may disappear during the tachycardia, or a *rough systolic murmur* may be added A final evaluation of the auscultatory findings of the heart, and the conclusions drawn from them, must therefore be delayed until the attack is over

The evaluation of *heart size* is today based on *x-ray* findings, which can be interpreted correctly only through comparison with films taken between attacks In uncomplicated cases, it can be demonstrated that the heart becomes *smaller* during the attack, which is what one would basically expect since diastole is relatively more shortened than systole (Dietlen; Groedel, Vaquez and Bordet). This is especially noticeable during a prolonged attack, and then atrial dilatation occurs as a result of venous engorgement and ineffective atrial contractions, a fact which is particularly true for the right atrium After termination of the attack, a return of the right atrium to normal size can be noted, although the size of the

rest of the heart increases. In paroxysmal tachycardia of long duration (or with a damaged myocardium), a *globular cardiac enlargement* can be observed. This indicates that the contractile strength of the ventricles is poor, so that the diastolic residual blood is increased even in the ventricles. After the attack, the dilatation of the heart regresses.

The enlargement of the heart is often associated with a widening of the large veins due to engorgement, particularly apparent in the region of the superior vena cava.

The *stroke volume* is greatly decreased in paroxysmal tachycardia. Barcroft et al., in two cases having a rate of over 200, found the stroke volume decreased from 77.5 to 12.9 cm^3, and the cardiac output from 5 to 6 liters to 2.1 to 2.8 liters/min. The elevated heart rate therefore cannot compensate for the decreased stroke volume, and the output is diminished to one-half or one-third of normal. The decrease of stroke volume can be explained by the inadequate filling of the ventricles. While at a rate of 50, diastole lasts twice as long as systole, at a rate of 150, it lasts only one-half as long as systole. With further increase of heart rate, as a result of *the relationship between heart rate and length* of diastole, theoretically a critical rate could be attained, in which the entire cycle would be occupied by systole. According to Bazett's and Hegglin-Holzmann *formulas*, this rate would lie between 260 and 370. Other factors render the attainment of such rates impossible in adults. The heart size plays a certain role because small human hearts with a high resting rate can tolerate remarkably well further increases in rate, while large hearts with a slow basal rate withstand relatively poorly lesser increases. Under otherwise normal conditions, the maximum tolerable rate is about three times the resting rate of a heart (v. Boros).

BLOOD PRESSURE. Usually there is a moderate drop of systolic pressure and no change of the diastolic pressure. This can be explained by the frequency of small pulse waves, obviously connected with short intervals, during which less of a diastolic drop is possible. The *coronary flow* is adversely affected by the paroxysmal tachycardia because the duration of diastole, during which a large part of flow takes place, becomes especially brief. The lowered aortic pressure is a further cause of deterioration.

Wégria and Keating induced paroxysmal tachycardia in a normal dog and observed a temporary backflow in the coronary vessels and a drop of the mean pressure. In moderately rapid tachycardias, both returned in a short time to the initial values or (uncommonly) even exceeded them. With very high rates, however, they remained low for the duration of the attack. The rates being equal, coronary flow and mean pressure are more severely decreased in ventricular than in supraventricular tachycardia. After termination of the tachycardia, mean pressure rises first and may become higher than normal.

Peripheral circulation is usually poor. Patients are pale and their extremities are cool. If there is concomitant heart disease and the attack is prolonged, cyanosis and venous engorgement are common.

Poor systemic circulation is followed by inadequate oxygenation of the blood and may be revealed dramatically by *Cheyne-Stokes respiration*. This disturbance may occur early in patients having heart failure, or, if there is no heart disease, it may be provoked only by episodes lasting several days.

A characteristic phenomenon is a *sudden, profuse diuresis*, which occurs at the end of an attack. The urine has a light color and a low specific gravity. This urinary flow may also occur in tachycardia associated with atrial fibrillation or flutter.

Blood gas analysis during an attack was made by Carter and Stewart, as well as by Dieuaide et al. They observed a moderate decrease of oxygen saturation in the arterial blood and a severe decrease in the venous blood. Accordingly, *the arteriovenous oxygen* difference was greatly increased.

A relationship between paroxysmal tachycardia and epilepsy was considered long ago. More recently, accurate studies were made with the aid of the EEG (Gérard, Naquet, Gras, and Jouve). In three EEGs taken during paroxysmal tachycardia, an increase of the rapid waves seemed likely, and there was a tendency to alleviation of the alpha waves. Between attacks, whatever the type of tachycardia, nothing could be seen in one-half the cases, and in the other half, there were only slight variations, such as absence of alpha waves. Specific changes similar to those of epi-

lepsy were not established either during an attack or in the intervals.

The Electrocardiogram. The ECG is, as a rule, characterized by the regular succession of ventricular complexes of supraventricular origin, usually with normal QRS duration and of normal pattern, at a rate of *150 to 220 in* the typical form, and of 120 to 150 *in* the moderate type. *The atrial waves have the same rate as the ventricular and have a constant relationship to the latter.* The configuration of the P waves is variable according *to* the origin in higher or lower parts of the atrium, as in atrial premature contractions (Fig. 11-2). In general, the *P* waves reveal that the stimulus is conducted in an upward direction. When no P waves are visible, they may be buried *in* the QRS complex or in the T wave of the preceding cycle. When the P *wave is hidden by the QRS* interval because of simultaneous activation of the atria and ventricles, there is an AV (nodal) origin of the stimulus. When the P wave is hidden in the T wave, there usually is delayed stimulation of the atria. These situations, as well as the difficulty of differentiating whether a negative P wave belongs to the preceding or the following cycle, have led to the adoption of the general term of "supraventricular tachycardia" instead of "atrial" or "nodal tachycardia." A differentiation often can be made only when one can observe the onset of an attack. If this begins with a ventricular complex *followed by a negative* P wave in lead II or III, or without any P wave, there is a nodal pacemaker.

In the form of extrasystolic paroxysmal tachycardia, the relationship of the atrial and ventricular complexes is basically *the same.* At the termination of the attack, *premature* contractions often occur. They have the same pattern as the complexes of the tachycardia. It is impossible to draw a sharp line of division *between a premature* contraction with repetitive formation and an extrasystolic tachycardia. In general, a run *of more than 6 to 10 extrasystoles is called* extrasystolic tachycardia.

The *relationship* between P waves and *ventricular complexes is similar* to that found in atrial, nodal, and ventricular extrasystoles. The *ventricular complexes* differ more or less from those of the normal sinus rhythm because of *slight flattening of the T wave and depression* of the S-T segment. Not infrequently, however, a *significant S-T* depression is noted and should be interpreted as the result of a *relative coronary insufficiency.* As this occurs also in young and healthy patients, it is not indicative of coronary artery disease. While precordial pain can be completely absent, a *typical ischemic pain* can be induced by the *tachycardia in patients with* coronary arteriosclerosis.

Occasionally, the ventricular complexes show an *alternating pattern* which usually involves both the form and the amplitude of the QRS complex.

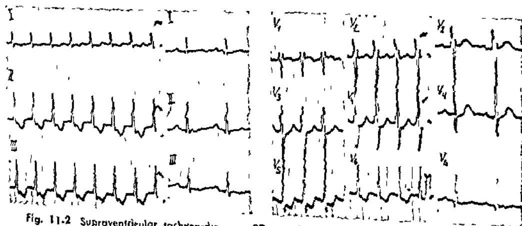

Fig. 11-2 Supraventricular tachycardia in a 37-year-old man without other abnormal cardiac findings. A After a 3-hr attack with a heart rate of 180. The position of the P waves can be established in lead V_1. B After an intravenous injection of 1.0 cm^3 of Mestinon and carotid sinus pressure, there is sinus rhythm at a rate of 95. Reflex slowing of the heart had been unsuccessfully tried prior to the injection.

In rare cases, the ventricular action may be irregular or slow, thus rendering the diagnosis particularly difficult. However the ECG will give the clue and solve the problem. The findings are.

1. *Irregularity of a supraventricular rhythm.* This is possibly connected with a variation of the P wave; it is usually the result of an extrasystolic type and is of moderate rate.

2. *AV conduction disturbances.* With changing rates, the conduction time can be slightly variable. If there is a 2° *AV block* with occasional dropping of stimuli, the picture of a tachyarrhythmia will take place. Poor AV conduction due to ischemia, infection, or digitalis glycosides predisposes to this picture. When there is a 3:1 or 4:1 type of block, the tracing may simulate that of atrial flutter. Finally, in complete AV block, the ventricular action is regular and slow.

3. *Addition of ventricular extrasystoles.* This occurs usually only at moderate rates, because otherwise the coupling is longer than the diastolic interval. There may be a combination of stimuli, so that ventricular activation is due partly to an extrasystolic focus and partly to a stimulus carried by the bundle of His. A rare occurrence is the combination of supraventricular and ventricular tachycardia

4. *Alternation* in the duration of AV interval is rare (10 out of 100 cases, Barker, P S, et al, 1943).

Complicated ECG findings can make the diagnosis of supraventricular paroxysmal tachycardia more difficult They may be the following.

1 *The patient already has a bundle branch block* This may give the impression of a ventricular tachycardia The problem is clarified only by the examination of previous or subsequent tracings Moreover, there are no P waves with a slower rate than the ventricular

2 *Intraventricular conduction disturbances* Strain of the ventricular conduction may cause variations of the intraventricular conduction, at times simulating the picture of bundle branch block It is important to note the constant relationship between the atrial and ventricular complexes The beginning of an attack is revealed by a premature P wave.

3 *Nodal tachycardia with interference dissociation* In a nodal tachycardia with retrograde block, it is possible that, occasionally, a P wave originating in the SA node finds the AV conduction system and the ventricles not in a refractory phase, thus resulting in a conducted beat. Since such ventricular complexes occur somewhat prematurely, they cause a slight arrhythmia. This sequence can be expected only in the type with moderate rate because of the longer refractory period of the ventricle (Schott, 1946).

Interpretation of the ECG can be clarified, at least in some cases, by *special observations* during and between attacks.

1. Observation, if possible, of the *beginning* or *end* of the attack, a feat which is less difficult in extrasystolic tachycardia than in the other types.

2. Depression of the rate or change of the conduction time, by means of *carotid sinus pressure,* so that the relationship of atrial and ventricular complex changes and P waves may be revealed. Blocking the AV conduction may reveal atrial flutter with rapid ventricular action. In atrial tachycardia, the P waves may appear, or the attack may be terminated.

3. The use of special ECG leads, particularly the *esophageal leads,* can reveal the P waves.

The *transition from paroxysmal tachycardia to sinus rhythm* (either spontaneously or following vagal stimulation) can occur in the following ways (Hellerstein and coworkers):

1. *A posttachycardic pause,* lasting several seconds and followed by sinus rhythm, is common

2 *The rate may become slower,* then suddenly change to a sinus rhythm

3 The transition can be *gradual.*

4. There is first a slowing, then a pause, and then the onset of sinus rhythm.

5 In the posttachycardic phase, one or more *nodal escapes* occur, then a few ventricular premature beats, possibly polyfocal, until sinus rhythm is reestablished.

Prolongation of the AV conduction and *aberrant ventricular response* can also occur.

The manner of termination of the attack is not always the same, even in the same patient. If during the tachycardia, there is a significant S-T depression, it usually disappears rather quickly However, if the sinus rate is still relatively high after the end of the attack, the depression lasts for a longer time After attacks lasting for several days, the ventricular com-

plexes often show some inversion of the T waves in various leads for several days or even weeks (*posttachycardial syndrome*).

Occurrence. Supraventricular paroxysmal tachycardia occurs at any age, however, it is relatively rare in newborn infants and young children There is no sex difference. Cases of familial occurrence have been reported.

The *frequency* of supraventricular paroxysmal tachycardia is difficult to determine, since some patients have never been checked during an attack, and others probably never realize that they are having an attack and therefore never report it

Kissane et al. analyzed the heart findings and clinical condition of 361 patients with supraventricular tachycardia, presenting the following data.

Percentage	*Finding*
34	No other illness demonstrable
34	Rheumatic heart disease
14	Arteriosclerotic heart disease
3	Hypertensive heart disease
5	Thyrotoxicosis
10	Other findings

The authors then compared these percentages with those of all the patients in their practice having these diseases From this, they realized that these attacks occur much more frequently in rheumatic than in arteriosclerotic heart disease, and that hyper- and hypothyroidism have no influence

The general experience is that, in at least one-third of the cases, the heart is normal

Mechanism. In order to explain paroxysmal tachycardia, we must consider the fact that the stimuli of either supraventricular or ventricular origin arranged in rapid sequence can occur with the same coupling as with individual extrasystoles No sharp distinctions can be drawn between runs of extrasystoles in series and paroxysmal tachycardia Therefore, premature contractions and paroxysmal tachycardia must have a similar mechanism

The theory of a *circus movement* was advocated by Mines Lewis refused to accept it in paroxysmal tachycardia His reasons were that it was not proved that extrasystoles were due to a circus movement, that the rate is lower than in flutter, that the stimuli were not necessarily arranged in series, and that no sufficiently long pathway was available in the atria to permit a circus movement at the necessary speed De Boer invoked the existence of the *bundle of Paladino-Kent* in order to explain supraventricular tachycardia. The stimulus would run upwards through the bundle of His and then over the accessory bundle back to the atrium, or in the opposite direction While this could be admitted in the Wolff-Parkinson-White syndrome, the explanation certainly is not valid for the other forms.

Ashman and Hull resorted again to the "circus" theory by admitting a *functional*, longitudinal dissociation in the bundle of His permitting both an atrial and a nodal pacemaker (in cases with retrograde conduction, possibly even a ventricular). A premature atrial beat would stimulate only part of the conduction system while the rest would still be in a refractory state. From the first group of fibers, *the stimulus would be transmitted* to the second and, through it, back to the atrium, which would again be stimulated.

The *theory of frequent heterotopic impulse formation* has more supporters today than the circus theory Scherf (1928, 1948, 1953), as well as Prinzmetal (1950, 1952), and their coworkers, have advocated this theory. The following points are presented in its favor:

1 In animal experiments, local application of barium chloride, digitalis, or strophanthin causes the formation of an extrasystolic focus. Warming of this focus is followed by paroxysmal tachycardia, which continues as long as the warmth is maintained (Scherf, 1948).

2. A circus movement within the atria is excluded because of the relationship between period length and speed of spread on the one hand, and length of the available path on the other (Lewis, 1925)

3 Sudden doubling or halving of the atrial rate (from 107 to 214—Camp and Scherf; a few observations from 90 to 180 and back) with unchanged P waves is compatible with a 2.1 exit block of the ectopic impulse.

4 The occurrence of an interference dissociation cannot be explained by a circus movement but is easy to explain by ectopic impulse formation (Schott, 1946)

Prinzmetal et al. (1950) provoked atrial tachycardia in the dog by means of chemical, electrical, and mechanical stimuli, and registered it on ECG moving pictures, and with the oscilloscope In all records, they found a spread of the impulse occurring in all directions. When they stimulated mechanically the atria of patients undergoing chest surgery,

In rare cases, the ventricular action may be irregular or slow, thus rendering the diagnosis particularly difficult. However the ECG will give the clue and solve the problem. The findings are.

1. *Irregularity of a supraventricular rhythm.* This is possibly connected with a variation of the P wave; it is usually the result of an extrasystolic type and is of moderate rate.

2. *AV conduction disturbances.* With changing rates, the conduction time can be slightly variable. If there is a 2° *AV block* with occasional dropping of stimuli, the picture of a tachyarrhythmia will take place. Poor AV conduction due to ischemia, infection, or digitalis glycosides predisposes to this picture When there is a 3:1 or 4:1 type of block, the tracing may simulate that of atrial flutter. Finally, in complete AV block, the ventricular action is regular and slow.

3. *Addition of ventricular extrasystoles* This occurs usually only at moderate rates, because otherwise the coupling is longer than the diastolic interval. There may be a combination of stimuli, so that ventricular activation is due partly to an extrasystolic focus and partly to a stimulus carried by the bundle of His A rare occurrence is the combination of supraventricular and ventricular tachycardia

4 *Alternation* in the duration of AV interval is rare (10 out of 100 cases, Barker, P. S., et al, 1943)

Complicated ECG findings can make the diagnosis of supraventricular paroxysmal tachycardia more difficult They may be the following.

1 *The patient already has a bundle branch block* This may give the impression of a ventricular tachycardia The problem is clarified only by the examination of previous or subsequent tracings Moreover, there are no P waves with a slower rate than the ventricular.

2 *Intraventricular conduction disturbances.* Strain of the ventricular conduction may cause variations of the intraventricular conduction, at times simulating the picture of bundle branch block It is important to note the constant relationship between the atrial and ventricular complexes The beginning of an attack is revealed by a premature P wave

3 *Nodal tachycardia with interference dissociation.* In a nodal tachycardia with retrograde block, it is possible that, occasionally, a P wave originating in the SA node finds the AV conduction system and the ventricles not in a refractory phase, thus resulting in a conducted beat Since such ventricular complexes occur somewhat prematurely, they cause a slight arrhythmia. This sequence can be expected only in the type with moderate rate because of the longer refractory period of the ventricle (Schott, 1946).

Interpretation of the ECG can be clarified, at least in some cases, by *special observations* during and between attacks:

1. Observation, if possible, of the *beginning* or *end* of the attack, a feat which is less difficult in extrasystolic tachycardia than in the other types.

2. Depression of the rate or change of the conduction time, by means of *carotid sinus pressure,* so that the relationship of atrial and ventricular complex changes and P waves may be revealed. Blocking the AV conduction may reveal atrial flutter with rapid ventricular action. In atrial tachycardia, the P waves may appear, or the attack may be terminated.

3. The use of special ECG leads, particularly the *esophageal leads,* can reveal the P waves.

The *transition from paroxysmal tachycardia to sinus rhythm* (either spontaneously or following vagal stimulation) can occur in the following ways (Hellerstein and coworkers):

1. A *posttachycardic pause,* lasting several seconds and followed by sinus rhythm, is common

2. *The rate may become slower,* then suddenly change to a sinus rhythm

3 The transition can be *gradual*

4. There is first a slowing, then a pause, and then the onset of sinus rhythm.

5. In the posttachycardic phase, one or more *nodal escapes* occur, then a few ventricular premature beats, possibly polifocal, until sinus rhythm is reestablished

Prolongation of the AV conduction and aberrant ventricular response can also occur.

The manner of termination of the attack is not always the same, even in the same patient. If during the tachycardia, there is a significant S-T depression, it usually disappears rather quickly However, if the sinus rate is still relatively high after the end of the attack, the depression lasts for a longer time. After attacks lasting for several days, the ventricular com-

is unsuccessful. Bilateral compression of the carotid should not be attempted since it causes cerebral anoxia. Unconsciousness and convul-

sinus pressure apparently was followed by cerebral thrombosis

If this maneuver is ineffective, *ocular pressure* should be attempted Intense pressure below the supraorbital ridges on the downward turned eyeballs is usually painful and should not be attempted on injured eyes. It causes a powerful *oculocardiac reflex.*

The success of these measures depends upon the skill of the operator and the type of attack. Success is claimed by various authors in from 10 per cent (White) to 80 per cent (Bellet) of cases If one of these methods works and the patient suffers frequent attacks, it is recommended that either he or the people around him be instructed in the use of the maneuver

MEDICATION *Parasympathomimetic drugs* Individual sensitivity to these drugs varies strongly Unpleasant side effects, such as nausea, vomiting, salivation, sweating, hyperpnea, and drop in pressure, can occur For these reasons, the following precautionary rules should be followed when these drugs are to be given by injection

1. The application should always be made with the patient lying down

2 A hypodermic syringe containing 0 5 to 1 0 mg *atropine* as an antidote should be ready for intravenous injection

3 Bronchial asthma and coronary sclerosis are contraindications

As all these drugs sensitize the vagal receptors, reflex vagal stimulation may become successful if tried a few minutes after their administration *Physostigmine*, 0 5 to 1 5 mg subcutaneously, has been used by Kaufmann (1912) (in combination with digitalis) and by de Meyer (in combination with strophanthin)

Prostigmine (*neostigmine*), 0 5 to 1.0 mg subcutaneously or intramuscularly, has proved successful (Waldman and Pelner) Intravenous administration should be avoided because dangerous The oral route is less reliable Abdominal cramps and diarrhea are common side effects.

Mestinon (pyridostigmine bromide), 1.0 to 2 0 mg intramuscularly, or 1 mg intravenously, or 20 mg four times a day orally, has a milder action.

Acetylcholine was recommended by Segers and coworkers (1945) as follows: intravenous injection of 20 mg (1.0 ml of 2 per cent solution), if this is without effect, the injection is repeated every 3 to 4 min with increasing doses of 40, 60, and 100 mg, as necessary. The effect usually occurs within 30 sec. Because a significant drop in blood pressure can occur, the patient should be supine and a syringe containing 0 5 to 1.0 mg atropine should be available.

Doryl (Merck) (carbaminol-choline-chloride) has been recommended similarly for intravenous injections (Birk, Lethaus, and Plugge). If ½ ampule (0 25 mg in 1 ml) is not sufficient, it can be repeated after a short time. The injection must be given very slowly in order not to cause a prolonged cardiac arrest.

Acetyl-beta-methylcholine (*Mecholyl*) was recommended by Starr (1933, 1936) and by Morgan in subcutaneous doses of 10 to 50 mg (average 25 mg). It is claimed that it terminates 90 per cent of the attacks. It should *not* be given intravenously. Its action becomes manifest within a few minutes. Side effects are more frequent and more severe than with acetylcholine, and even fatalities have occurred. With the transition to sinus rhythm, a short ventricular tachycardia of the fibrillatory type can occur (Bellet).

Strophanthin may terminate an attack immediately after one intravenous injection of 0 75 mg (Volhard), or one to two injections of 0 5 mg or three to four injections of 0.3 mg (Edens and Weese). Possible dangers of such large doses should be considered, especially if there has been previous digitalization or if the patient has coronary sclerosis.

Digitalis preparations are preferred today in the treatment of supraventricular paroxysmal tachycardia (Wilson and Wishart; Bohnenkamp). Intravenous injection of 0 8 to 1 6 mg *Cedilanid* can result in a sudden interruption of the attack (Kroetz) or in its arrest within 20 min (Weissberger and Feil). A similar effect can be obtained with *digitoxin* or *acetyldigitoxin* (*Acylanid*) in dose of 1 3 to 2 0 mg in one to two intravenous injections (Spang, Loeffler et al).

they repeated the same observations for both extrasystoles and tachycardia.

Pathologic Findings. Occasional deaths of patients with supraventricular tachycardia have revealed gross anatomic findings corresponding to the accompanying disease. In other accidental deaths, these findings have been absent. Precise histologic examinations are rare. Most of the studies have revealed changes in the area of the SA node, the atria (especially the right), the AV node, and the bundle of His.

Mackenzie (1908) described a case with obliteration of the nutrient artery of the AV system, and a case with fibrotic changes in the SA node. Cade and Rebattu (1911) described a case with round cell infiltration and connective tissue hyperplasia in the bundle of His. Butterfield and Hunt studied a case with cell infiltration of the wall of the right atrium, including the SA node. Falconer and Duncan examined the heart of a case with interstitial lymphocyte accumulation in the right atrium, SA node, and AV node area Mahaim (1932) studied a 14-month-old child who had suffered from an uncontrollable supraventricular tachycardia following influenza. In the right atrium, widespread foci of lymphocytes and polymorphonuclear leucocytes, which had involved the SA node region, were found Piotti (1945) studied an 11-month-old child, who had suffered from a sustained supraventricular tachycardia for 7 months, and found interstitial myocarditis (Fiedler type) involving the right atrium and particularly the area of the coronary sinus

Prognosis. The prognosis of the supraventricular tachycardia is usually good Death during an attack is rare However, it may occur in cases with myocarditis or coronary heart disease.

The prognosis should be guarded if a serious heart condition is present, particularly coronary heart disease. If the blood pressure is low, the dangers represented by prolonged or frequent attacks are greater Among other complications, thromboembolic phenomena may occur In these cases, the prognosis is based upon the speed and efficacy of treatment.

In normal hearts, even prolonged and frequent attacks are well tolerated. Noteworthy are the cases in infants and adolescents who may have prolonged extrasystolic tachycardia lasting even 10 years without permanent damage and finally disappearing.

The *life expectancy* is not shortened by paroxysmal tachycardia in an otherwise normal heart. Campbell and Elliot found among 100 cases, 3 who experienced paroxysmal tachycardia for longer than 50 years, and 18 who had it for longer than 20 years. Cooke and White observed a man, still active at 72, who had suffered attacks of paroxysmal tachycardia since the age of 7. It is possible that paroxysmal tachycardia which starts at an older age should be considered more seriously. While Campbell and Elliot admit this point, Cooke and White (1942) find no difference in the prognosis whether the first attack occurred before or after the fortieth year of age.

Treatment. Medical management has two objectives: cessation of the attack and prevention of its repetition.

The treatment of the attack is frequently successful in the supraventricular paroxysmal tachycardia and is based on *reflex stimulation of the vagus nerves.* Often the patient himself has discovered certain means of depressing the attack and the physician can use similar methods. If they do not succeed, he can resort to well-known methods of vagal stimulation If these also fail, certain drugs are available which will either stop the attack or act within a short period of time. In the greatest number of cases, these means are successful, reflex stimulation should always be tried first If one resorts to medication, one should begin with the most harmless.

THE MECHANICAL REFLEX INFLUENCES Certain methods have been shown to be of benefit in individual cases These are curling of the body, lying down with the head below the level of the body, strenuous tensing of the abdominal muscles, the Valsalva or Muller maneuvers, production of nausea by stimulation of the palate, or drinking of iced water. If these measures do not suffice, stronger *reflex vagal stimuli* should be attempted Since before the establishment of a sinus rhythm, a significant "preautomatic" pause can occur, with at times a cardiac arrest of a few seconds, these measures should always be undertaken with the patient lying down

Carotid sinus pressure is in general the most effective It should be done with constantly increasing intensity while monitoring the heart action and should be discontinued as soon as the tachycardia disappears, so that an unpleasant cardiac arrest will be avoided. First, one should try one side, then the other. Repeated stimulation of the same side generally

VENTRICULAR TACHYCARDIA

The Clinical Picture. In contrast to the supraventricular form, these attacks, as a rule, occur in individuals having cardiac disease They are, therefore, only part of the clinical picture, may be unrecognized by the patient, and often are not properly evaluated by the physician, at least in a first period.

The duration of the attack may vary. Most episodes last from a few seconds to several days Attacks lasting from 3 to 4 weeks are not unusual The longest ventricular tachycardia, lasting 77 days, was described by Mays

If an episode of ventricular tachycardia has occurred once, *there is a tendency for its repetition* These attacks can occur either after brief intervals or, on the contrary, only after several years They may tend to become more frequent with time On the other hand, there may be a single episode—e g , after a coronary occlusion, followed by permanent recovery or, at times, having a fatal outcome

Symptoms and Signs They vary considerably according to the underlying heart disease and the duration of the attack If there has been heart failure, ventricular tachycardia may be completely unapparent and masked by the general picture If the attack lasts for several days, increasing signs of circulatory insufficiency, such as *dyspnea, somnolence,* and *pain in the right hypochondrium,* often occur If the attack follows an infarct, either a *status anginosus* (persistent precordial pain) or a sudden *collapse* may be the consequence

Occasionally, certain clinical *signs* indicate the nature of the tachycardia They are not always present, however, and at times may be doubtful, so that the final diagnosis is always made through the ECG.

The ventricular rate can be determined by simultaneous auscultation of the heart and palpation of the pulse It is usually between 160 and 180, but it may be as low as 125, particularly under the influence of medication On the other hand, if ventricular flutter occurs, the rate may exceed 200

The cardiac rhythm may be completely regular Several authors (particularly Strong and Levine, S A , 1927) emphasize that ventricular tachycardia is less stable than the supraventricular However, they most likely refer to cases of extrasystolic tachycardia with short pauses, during which single extrasystoles occur. In these cases, one has the impression of a considerable arrhythmia, even simulating that of atrial fibrillation.

On auscultation, *the heart sounds show different degrees of loudness if the atria are still ruled by a SA pacemaker.* Levine (1921) showed that the 1st heart sound presents periodical changes of intensity. As in complete AV block, the 1st heart sound is louder (*cannon sound*) if the atrial and ventricular contractions occur at the same time or if the atria contract 0 05 to 0.12 sec before the ventricles (Duchosal). Obviously, this phenomenon does not occur if there is atrial fibrillation or retrograde atrial stimulation Apart from these cases, periodic intensification of the 1st sound is demonstrable in about 50 per cent of the cases (Armbrust and Levine).

Another phenomenon occasionally determined at auscultation may be *misleading: only* the 1st sound may be heard, or even more misleading, its loudness may alternate (Armbrust and Levine) Then, it is possible that only *one-half* of the ventricular beats are counted. The peripheral pulse can *sometimes* clarify the situation, the ECG always does so.

The *arterial pulse* is mostly small and often difficult to palpate Occasionally, it shows a *periodic intensification* If one can exclude any connection with respiration, such a finding is typical of ventricular tachycardia. The larger pulse waves occur when an atrial contraction falls at the end of a ventricular systole or with a short ventricular diastole, while the pulse is small or absent if the onset of the atrial contraction occurs at the beginning of a ventricular systole (Fischer; Lian et al., 1931; Zeh) When an atrial contraction occurs simultaneously with a ventricular, it forces the blood backwards into the large veins and there is less venous return shortly thereafter, so that the subsequent ventricular filling is decreased. In cases with dissociation, the arterial pulsations were recorded graphically and found to be decreased when the R-P interval was between 0 06 and 0.18 sec.

In the *venous tracing,* a tall wave can be observed at the time of the "cannon sound" (Gallavardin, 1920) Careful inspection of the jugular veins reveals pulsations which occur at about *one-half* the rate of the ventricular systoles as determined by auscultation, and

Because the digitalis, in addition to its direct action on the heart, decreases the threshold of the carotid sinus, it is worthwhile to press the carotid sinus again 20 to 30 min after the injection, in case the desired result has not occurred. This should always be tried before further digitalis injections are given. Digitalis therapy is indicated if the tachycardia occurs in a damaged heart or in the presence of congestive failure, and if the reflex vagal stimulation was unsuccessful.

Quinidine acts by depressing all properties of the heart. It should not be used if there is heart failure but can be resorted to in other cases if carotid pressure and digitalis have failed. Quinidine is given orally as *quinidine sulfate* in dose of 0.4 Gm four to six times daily. If the oral route cannot be used or rapid action is necessary, *quinidine gluconate* 0 4 Gm can be given intramuscularly (Bellet) and repeated after 2 hr if necessary. The intravenous approach is not advisable because of possible unpleasant side effects

Magnesium sulfate acts like quinidine; 10 to 20 ml of a 20 per cent solution can be injected intravenously within ½ to 1 min (Zwillinger, Boyd and Scherf) The injection is accompanied by a sensation of warmth and can be followed by a significant drop in blood pressure. Before the end of the tachycardia, conduction disturbances and ventricular extrasystoles may occur With severe myocardial damage and intraventricular conduction disturbances, magnesium sulfate should be avoided.

Procaine amide (Pronestyl) is similar in action to quinidine It is especially indicated in ventricular tachycardia but has been recommended also in supraventricular tachycardia. According to Bellet and coworkers (1952), it is effective in 80 per cent of the cases.

Sedatives with sympatholytic action have been used (Szutrély and Voltay) One mixture is the so-called "*lytic cocktail*" of Laborit and Huguenard, which is composed of Largactil/Phenergan/Dolantin in the ratio of 1:1:2 and is given intravenously at an approximate dosage of Largactil of 0.6 mg/kg.

Sympathomimetics, like *Neo-synephrine,* are occasionally effective This illuminates the multiple influences which are possible. The sympathicomimetics stimulate the carotid sinus through a blood pressure rise and thus produce vagal stimulation. In case 0.5 mg intravenously does not work, a double dose can be tried, except in cases of hypertension and coronary sclerosis (Youmans and coworkers).

Other drugs have been used occasionally but have no practical importance They are *adenosine* (Kalaja), *fagarine*[1] (Scherf et al, 1949, Silver and Weinberg; Taquini), *Veratrum viride* (Shaw), *calcium gluconate* (Wolffe and Bellet), *Atabrine* (Gertler and Yohalem).

Surgical procedures have been attempted in patients with a great frequency of attacks. Leriche et al. (1935) recommended *left stellectomy.* According to White and Bland, the ganglion chain should be removed bilaterally from the stellate ganglia downwards to the fourth or fifth thoracic ganglion. *Alcohol injection* into the ganglia can be effective, but the attacks may recur after regeneration of nerve fibers (Coleman and Bennett).

PROPHYLACTIC MEASURES FOR THE PREVENTION OF ATTACKS. When any precipitating factor is known in a particular case, such as overeating, alcohol, smoking, coffee, constipation, certain body positions, or psychic stimulation, it should be eliminated.

In resistant cases, *medical means* should be added. The same drugs which have been described to terminate an attack can be given in small doses for this purpose. Basically, the smallest dose which may prevent an attack should be used.

Of the *vagomimetics,* particularly good are *Doryl* or *Mestinon* in tablet form. It is recommended to begin with three tablets daily.

Digitalis is the drug of choice if the attack has not occurred under previous digitalization, and if heart failure is present

Quinidine is to be recommended in patients without heart disease. Association with phenobarbital often proves useful

Procaine amide with an initial dose of 250 mg three to four times, is also to be considered.

Rauwolfia alkaloids are not effective in terminating an attack but may be effective prophylactically. *Serpasil,* 0 1 mg, three to four times daily is the usual dose for children, 0.25 mg three to four times daily for adults (Bixby, Szutrély and Voltay).

[1] Fagarine may cause ventricular fibrillation and should not be used in clinical cases. *Editor.*

systoles between attacks as during an attack *indicates* ventricular tachycardia

The ECG can show other characteristics:

1. *Alternating ventricular complexes can occur.* There may be a *monophasic*, homolateral alternation consisting of changing amplitude of part of the ventricular complex, or a *diphasic*, bilateral alternation consisting of a change of polarity of the ventricular complex and indicating alternative pacemakers in the two ventricles (Fig. 11-4). The latter is encountered especially under the action of digitalis glycosides. The duration of the ventricular complex may be stable or alternate.

2. *The ventricular complexes may be polyform.* Then the ventricular action is generally irregular and, as a rule, is associated with atrial fibrillation (Fig 11-3A). These tachyarrhythmias represent a dangerous condition, which usually is followed by ventricular flut-

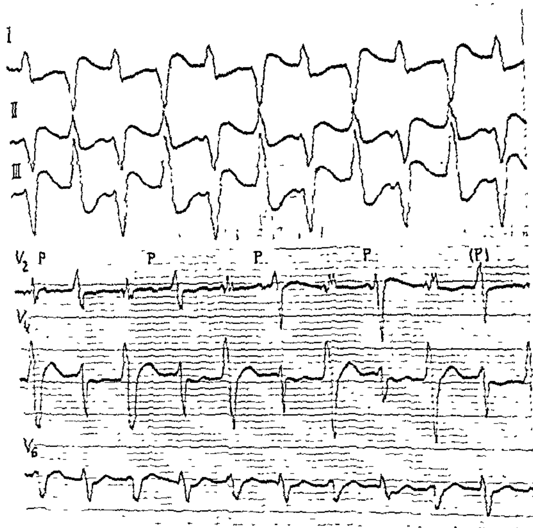

Fig 11-4. Paroxysmal alternating ventricular tachycardia in a 55-year-old man with decompensated hypertension after a 10-day treatment consisting of daily intravenous injections of 0.25 mg Strophosid, 0.25 Gm Euphylline, and 10 ml of 5 per cent glucose. Mean ventricular rate, 143 to 153. The phasic alternation is most marked in the limb leads The independence from a sinus rhythm is demonstrated by the "wandering" P waves in the precordial leads There is at times a definite alternation of the ventricular complexes The ventricular tachycardia disappeared after discontinuation of strophanthin. The patient died 2 months later. At autopsy, severe bilateral hypertrophy with fatty degeneration of the myocardium, a subacute infarct in the left papillary muscle, and renal arteriosclerosis were found.

which periodically increase and decrease in amplitude independently of the respiration. These pulsations will be revealed even better, however, by recording a *jugular tracing* and are due to superposition of the A and C waves.

The changes of *heart size, stroke volume,* and *blood pressure* are the same as in supraventricular tachycardia. During the clinical taking of blood pressure, a periodic increase of the pulse can occasionally be demonstrated (see above).

With the auscultatory method, arterial sounds are generally audible only at long intervals corresponding to a periodically increased systolic pressure. With the oscillometer, this phenomenon is designated as "nonalternating anisosphygmia" (Lian et al., 1931).

The effect of the tachycardia on the peripheral circulation is in general more severe than in supraventricular tachycardia because usually the heart is damaged Somnolence and Cheyne-Stokes respiration are more frequently observed. Exceptionally, tachycardia may be followed by gangrene of the fingers or toes (Abrahams).

The Electrocardiogram. The typical picture of ventricular tachycardia shows ventricular complexes similar to ventricular extrasystoles in rapid and regular (or almost regular) sequence; *there are P waves recurring at a slower rate* (Fig. 11-3B, C). The shape of the ventricular complexes in the various leads depends upon the site of the ectopic pacemaker, as in the case of extrasystoles For their recognition, the same methods should be employed. Theoretically, the tachycardia could originate in the basal portion of the ventricular septum or at the origin of the bundle of His, so that a normal pattern of ventricular stimulation could occur. Furthermore, the P waves can be absent if there is atrial fibrillation in addition to the ventricular tachycardia.

If the demonstration of a rapid ventricular rate, independent of SA stimulation, cannot be obtained, finding the same coupling for extra-

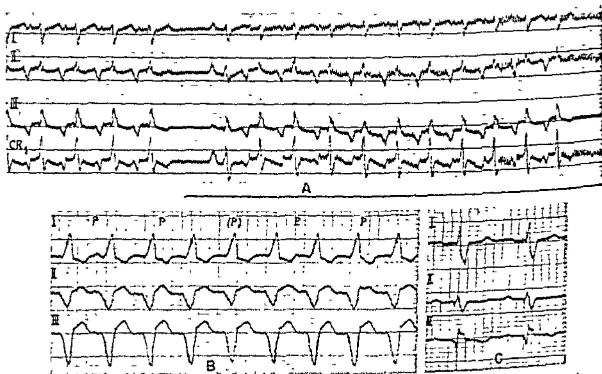

Fig. 11-3. A Supraventricular tachycardia in an 8-year-old girl Obstinate and frequent attacks. Inverted P waves in leads II, III, and CR_1 Because the AV interval is 0 14 sec, the pacemaker must be in the caudal portion of the atria With carotid sinus pressure (white flap), the tachycardia can be interrupted for short periods. However, after one ventricular complex of sinus origin, the attack starts again. B. Ventricular tachycardia in a 75-year-old man with a myocardial infarct. For 4 days there was a right ventricular tachycardia at a rate of 133. The P waves fall before, within, or after the QRS complexes at a rate of 70. C. Same case as in (B), after Pronestyl (0.5 Gm, four times). Sinus rhythm at a rate of 70, prolonged AV conduction, and right bundle branch block.

ter and fibrillation (*prefibrillatory phase of Gallavardin* or *ventricular anarchy of Clerc and Levy*).

3. If the ventricular stimuli follow each other in rapid sequence, so that their beginning and end can no longer be distinguished, and if, moreover, diphasic undulations occur, then ventricular tachycardia has become *ventricular flutter*.

4. A retrograde conduction to the atria, as a rule, does not occur; however, since no AV block is present, a *pararrhythmia* may arise, causing an *interference dissociation*. As a result of the high ventricular rate, and probably as a result of penetration of impulses into the lowest portion of the conduction system rendering it refractory, there is very seldom an AV conduction If such a conduction exceptionally occurs (particularly when the ventricular rate is moderate), it is revealed by a few premature ventricular complexes without the typical bundle branch block appearance, or by *fusion beats* when the rates are similar, so that the ventricles are stimulated partly through the bundle and partly by an ectopic ventricular focus (Holzmann)

5 In rare cases, a *retrograde conduction of the ventricular impulse to the atria can be observed*, similar to that which may occur in ventricular extrasystoles Then, negative P waves can be seen in leads II and III following the QRS complexes The retrograde mechanism becomes especially clear if the retrograde conduction is combined with a *second-degree retrograde block with Wenkebach periods*. Then, the ventricular complexes continue undisturbed while the negative P waves migrate farther and farther from the QRS complex until one is dropped and the sequence begins again (Fig. 11-6). In the *differential diagnosis* of this form, one should consider supraventricular tachycardia, as well as atrial fibrillation and flutter, with previous bundle branch block, or a functional bundle branch block caused by the tachycardia. Tracings recorded before the attack are, therefore, always extremely helpful.

If there is considerable variability of the ventricular rate, *atrial fibrillation with a functional bundle branch block* should be excluded before admitting a ventricular tachycardia. If atrial fibrillation with conduction to the ventricles was present prior to the attack, the assumption of ventricular tachycardia is justified by the appearance of an independent ventricular stimulation occurring *by attacks*. There are, however, cases of atrial fibrillation with severe variations in the AV conduction and with a threshold value of the conduction in the bundle, which causes this to become deficient if the rate is high The more regular and rapid the ventricular rate, the more likely is the assumption of ventricular tachycardia. This may be confirmed by finding ventricular complexes with the same coupling as that of extrasystoles between attacks.

Supraventricular tachycardia with a second-degree AV block can simulate runs of ven-

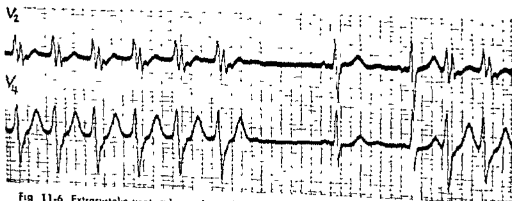

Fig 11-6 Extrasystolic ventricular tachycardia in a *62-year-old* woman, range from 143 to 153. Retrograde conduction to the atria with Wenckebach periods The *second* ventricular complex shows no retrograde conduction The RP measured 0.1[illegible]

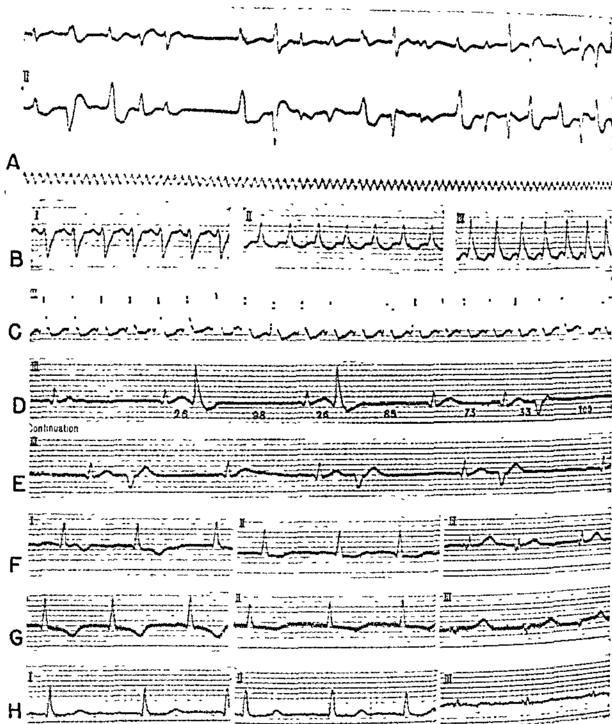

Fig. 11-5. A Complete ventricular anarchy in a woman, aged 60, who was suffering from chronic rheumatic carditis and circulatory failure (autopsy was performed 3 days later). Atrial fibrillation. Complexes of supraventricular origin (first and sixth) with variable ventricular conduction paths; ventricular tachycardia with irregular complexes. B. Left-sided ventricular paroxysmal tachycardia in a 50-year-old woman with myocardial disease of unknown origin. During the attack: ventricular rate, 227 C Immediately following intravenous injection of quinine hydrochloride, gr 7½ (0 5 Gm); ventricular rate, 240 Variable irregularities in the S-T segment suggest atrial fibrillation D. 40 sec later; atrial fibrillation. Marked abnormality of the ventricular complexes at irregular intervals, with ventricular extrasystoles. E 5 min later atrial fibrillation with myocardial damage, particularly of the left ventricle. F. 2 days later; ventricular complexes even more abnormal. G. 4½ months later; atrial fibrillation. Regression of posttachycardia syndrome. (*From Holzmann. Klinische Elektrokardiographie,* 1955.)

in chronically ill cardiac patients in the hospital

The attacks are favored by advanced age. While some cases have been observed in the second decade, most of them occur between 50 and 70 years of age

The *male sex* predominates, about two-thirds of the cases occur in males.

Ventricular tachycardia can occur either with sinus rhythm or with fibrillation. Exceptionally, it can also follow a supraventricular tachycardia (Barker, P S).

Usually, though not always, the attacks occur in patients with a severely damaged myocardium; in about one-half the cases, the clinical picture of congestive failure either exists or supervenes

In a statistical study of 107 cases of paroxysmal ventricular tachycardia, Armbrust and Levine found the following·

Finding	*No of Cases*
Coronary artery disease	79 (74%)
Rheumatic heart disease	9
Congenital heart disease	1
Wolff-Parkinson-White syndrome	5
No evidence of heart disease	13 (12%)

During *severe infections,* such as diphtheria, rheumatic fever, or streptococcal infections, ventricular tachycardia may be observed in children

Epinephrine and large doses of quinidine or *Pronestyl* can provoke attacks

Overdose of *digitalis glycosides* may precipitate ventricular tachycardia, and even moderate doses may do so in a severely damaged myocardium This is not astonishing, for digitalis favors the formation of ventricular pacemakers Since digitalis intoxication in normal individuals does not cause ventricular tachycardia, preexisting myocardial damage is essential in the causation of this disturbance

According to general experience, patients with an otherwise normal heart were encountered mainly in the younger age groups Campbell and Elliot found an apparently normal heart in 8 of 11 patients under 40 but in only 2 of 31 patients over 40 years of age

The following etiologic-clinical classification of the ventricular tachycardias is after Froment

1. *Ventricular tachycardia in cases with severe myocardial disease*
   a. *Cases with septal lesions.* They usually follow a recent myocardial infarction involving the septum, but may occur without it. Rarely they are due to syphilitic myocarditis involving the septum. They occur mostly in advanced age, and the ECG usually has a constant configuration. The prognosis is rather poor.
   b. *Cases with terminal, prefibrillatory tachycardia.* This form is observed in patients with severe congestive failure, often follows previous brief runs of tachycardia, and is revealed by a polymorphic aspect in the ECG. The prognosis is very poor.
2. *Ventricular tachycardia in clinically normal hearts·*
   a. *Extrasystolic type* (*extrasystolie ventriculaire en salves,* Callavardin) with onset during youth and with a course which may be either benign or obstinate, even lasting for more than 30 years.
   b *Essential type* (Bouveret-Hoffmann), with less frequent but longer attacks, which usually begin during youth and which may have a course of many years The prognosis is good.

Mechanism. The possibility of a circus movement cannot be admitted because there are no pathways between the ventricles The cases which present ventricular extrasystoles between attacks having the same coupling and pattern confirm that both the tachycardia and the extrasystoles have the same mechanism, i e , a heterotopic focus of impulse formation or a reentry phenomenon.

Pathology. Upon gross examination, there is no typical finding in cases of ventricular tachycardias However, lesions of the ventricular septum are rather frequently encountered, and microscopic lesions consisting of inflammatory or degenerative changes in the network of Purkinje or in the AV node, the bundle of His, and its branches are extremely frequent (Mahaim, 1932). It is logical to consider that these lesions represent the anatomic basis of the attacks of tachycardia. This assumption explains why not infrequently ventricular tachycardia and AV block release each other The former corresponds to a stimu-

tricular tachycardia, if several stimuli are conducted one after another, and cause a functional bundle branch block.

MOBITZ'S INTERFERENCE DISSOCIATION. A pararrhythmia of sinus and node activity with additional *functional bundle branch block* can be recognized because the prematurely conducted ventricular impulses also show the bundle branch block pattern.

Not infrequently, a definite decision as to the underlying mechanism cannot be made from a single ECG finding. Then, the following methods may be used:

1. *Reflex vagal stimulation* This barely influences ventricular tachycardia, or affects it not at all, whereas it may terminate supraventricular tachycardia (a functional bundle branch block would disappear), or so depress AV conduction that AV block occurs (the rapid atrial activity becomes visible) and fibrillation or flutter waves are unmasked.

2. *Esophageal leads* may clarify the relationship of the ventricles and atrial complexes by revealing the latter with a higher voltage.

3 *Pronestyl* can contribute to the diagnosis by overcoming a ventricular tachycardia

The *differential diagnosis* between supraventricular and ventricular tachycardia can be made, up to a certain point, by observing the characteristics of the rhythm, the heart sounds, the arterial and venous pulses and, above all, through the electrocardiogram. Reflex vagal stimulation can be informative (Table 11-1).

Occurrence. Paroxysmal ventricular tachycardia is rare in office practice, but it is often encountered during acute heart attacks and

TABLE 11-1 DIFFERENTIAL DATA OF THE TACHYCARDIAS

	Supraventricular	*Ventricular*
I Rhythm	A *Regular* (essential type) Exceptions—irregular with· 1. Second-degree AV block 2 AV tachycardia with interference dissociation B *Irregular* (extrasystolic type)	A *Either regular or slightly irregular* (essential type) B. *Severely irregular* (extrasystolic type)
II. Auscultation	First heart sound of constant loudness (may not be so in I A.)	First heart sound periodically increased (except with retrograde atrial stimulation or atrial fibrillation)
III Arterial pulse	Equal	May be periodically increased
IV. Jugular tracing	Constant large pulsations (may not be so in I A)	Periodical atrial waves (except that retrograde atrial stimulation will cause nonperiodic waves while atrial fibrillation will cause their disappearance)
V Electrocardiogram A Atrial complex	*P wave in constant relationship to the ventricular complexes* (except in the presence of block and in AV tachycardia with interference dissociation)	*P wave independent of the ventricular complexes* (except with retrograde atrial stimulation; the P waves will be absent if there is atrial fibrillation)
B. Ventricular complex	*Ventricular complexes of conducted type* normal QRS duration (except if there already is bundle branch block or if a functional bundle branch block is caused by the tachycardia)	*Bizarre ventricular complexes,* QRS interval prolonged and deformed (except if the stimulus originates in one stem of the [illegible] lation with a functional bundle branch block, and tachycardic atrial fibrillation with conduction through an abnormal AV pathway (Wolff-Parkinson-White syndrome)
VI Reflex vagal stimulation	Often effective by: A Terminating the attack B. Blocking the AV conduction (rare)	Ineffective

should be given with the blood pressure under *continuous control* and the ECG *under constant observation. The injection of 1 Gm should* be given very slowly (at about 0.1 *Gm* every 2 min). If the attack is terminated after only part of the above dosage is given, the administration can be discontinued. The injection should be *interrupted* if the ECG shows *evidence of a definite* increase in the duration of the *QRS* complex or if there is a significant drop in blood pressure. Since several fatalities have been reported following the *intravenous* administration of Pronestyl (generally with rapid administration), the intramuscular *injection is preferred* in several institutions as *being less* dangerous. For this, 0.5 to 1.0 Gm is *injected*, and the injection can be repeated one to *three times* at 1- *to* 4-*hour* intervals until the tachycardia is controlled. If there is no special cause of worry, the oral route can be employed. With *doses* of 0.5 Gm every 2 hr, or 1 Gm every 4 hr, the attack may be terminated within a period varying from hours to days in about 70 per cent of cases (Bellet *et al.*, 1952).

Quinine, quinidine, and Pronestyl are contraindicated in cases where there has been an AV block.

Digitalis favors the formation of ectopic foci in the ventricles. However, it *is occasionally* capable of causing the disappearance of a ventricular tachycardia, *apparently* by improving the circulation, through a prolongation of *the refractory period*, and through a decrease *of conduction* (*Scherf* and Kisch, Gilson and Schemm). Obviously, this drug cannot even be considered if the attack has occurred while the patient is under digitalis therapy or in a prefibrillatory state with *multifocal* ventricular complexes. If this is not the case and heart failure is present or *there is low blood pressure*, digitalis can be used.

Potassium salts, on the contrary, are specifically *indicated in* paroxysmal *ventricular tachycardia favored* by overdigitalization, because *during toxic digitalis action, an intracellular decrease of potassium and magnesium ions occurs*. Under such conditions, an attack can be terminated by the administration of 2 Gm potassium chloride or citrate *every 2 hr or* by the careful intravenous *infusion of an isotonic* potassium *chloride solution*. *Overdosage* should be *prevented by* determination of the serum potassium levels and through observation of the ECG.

Magnesium sulfate is similarly worth a try, particularly in ventricular tachycardia *under* the effect of digitalis (Zwillinger, Boyd and *Scherf; Szekely and Wynne*). As with *premature beats caused* by digitalis, 15 to 20 ml of a 15 to 20 per *cent solution* of magnesium sulfate should be *injected slowly into a vein*.

Morphine has been recommended by Gonzalez Sabathié (*intravenous injection of* 10 to *40 mg*); *papaverine* has been advocated by Elek *and Katz*.

Atropine. Atropine sulfate (*1 to 2 mg*, intravenously or *intramuscularly*), *alone or in combination* with *quinidine, has also* been *successful in some cases* (Salley; Levine, 1945). Atropine is generally administered only when the ventricular rate has already *significantly decreased through the use of quinidine*. Its action seems *based on* a prolongation of the refractory period.

COMPLICATIONS OF THE PAROXYSMAL TACHYCARDIAS

Heart failure can be induced by prolonged attacks *of the rapid forms of tachycardia. This* occurs *particularly* in ventricular tachycardia when the heart has been previously damaged. *Pulmonary edema* (possibly associated with pulmonary infarction) and hepatic engorgement, followed by abdominal distention and ascites, *usually disappear rapidly after the end of the attack, unless* the *previous* cardiac condition *was* too poor. Cardiac glycosides may be necessary but should be administered with caution.

A myocardial infarct may be the *result of a* prolonged paroxysmal tachycardia *in cases* with *coronary stenosis. Precordial* pain can reveal *this occurrence*, *although* such pain may be absent if there is a simultaneous onset of failure. After each prolonged attack of tachycardia, one should examine the temperature, white cell count, blood *pressure*, transaminase activity, sedimentation *rate*, and *ECG*, in order to exclude the *occurrence* of a myocardial infarct.

Electrocardiographic evidence of coronary *insufficiency may* last from *minutes* to hours after the attack is over and *is* present particularly in cases with poor coronary flow *and* ventricular hypertrophy *or other myocardial le-*

lation, the latter to a functional depression of the conducting system. Observations in cases with myocardial infarcts reveal that the ventricular septum is a preferred site from which ventricular tachycardia can be elicited. It is not known how far the histologic changes that produce ventricular tachycardias spread into the periphery.

There is, so far, no anatomic proof of congenital abnormalities in cases of obstinate extrasystolic tachycardias with good prognosis (Parkinson and Papp).

Prognosis. The prognosis of ventricular tachycardia depends primarily upon the underlying cardiac condition. It is severe in patients where the attack is provoked by a *fresh myocardial infarct.* Among 42 such patients of Armbrust and Levine, 28 (or 64 per cent) died within 1 month, 10 lived longer than 2 years, and the longest survival was for 11 years. The outlook has considerably improved with modern therapy, including anticoagulants, treatment of shock, and treatment of the tachycardia itself, *if immediate treatment is given.* Even today, prognosis is severe for patients who have a cardiogenic shock during the attack of tachycardia. The same is true for the ventricular tachycardia during infections, because the attack reveals the existence of myocarditis The outlook is extremely poor if the ventricular tachycardia occurs during an advanced stage of *heart failure.* In younger patients, this is usually due to chronic myocarditis; in older cases, the underlying basis is generally a degenerative process due to coronary heart disease (and often an old infarct). The designation of these types as *terminal* reveals their prognosis According to Strauss, 80 per cent of such patients die within 24 hr, according to Cooke and White (1943), one-half of such patients die within the first 3 weeks and the other half within the next few months, the longest survival being for 18 months. The immediate prognosis is somewhat better if the paroxysmal tachycardia occurs during therapy with digitalis glycosides. Then, discontinuance or modification of therapy can affect the tachycardia. Even so, the outlook remains poor on account of poor myocardial conditions.

In relatively rare cases with *apparently normal hearts,* the prognosis is considerably better, though occasional fatalities during an attack occur even in such cases, apparently through transformation of the ventricular tachycardia into flutter and then fibrillation

Treatment. Certain measures effective in supraventricular tachycardia are also effective in the ventricular form; others, however, fail. Certain medications are specifically indicated in ventricular tachycardia. Since the prognosis becomes worse with prolongation of the attack whenever the heart is damaged, treatment should be instituted immediately.

Reflex vagal stimulation and parasympathomimetic drugs are worthless, as they do not influence a ventricular ectopic focus. In spite of this, carotid sinus pressure should be tried in order to exclude a case of supraventricular tachycardia with an equivocal ECG picture. If unsuccessful, it will confirm the diagnosis of a ventricular form. On the other hand, no time should be lost while trying vagal stimulating drugs.

Quinidine can be tried as in supraventricular tachycardia. If the general conditions are severe, one should not wait for the effect of an oral therapy but should employ, instead, a more rapidly acting intravenous preparation: *quinidine lactate,* 0 6 Gm in 200 ml of 5 per cent glucose at a speed of 2 to 3 ml per min (Kantner), or *quinidine gluconate* or *hydrochloride,* 0.3 to 0.8 Gm in 20 to 100 ml of isotonic saline solution injected through not less than 10 min (Bellet et al., 1949), or a slow injection of *quinidine dihydrochloric carbamide,* 0.3 to 0.5 Gm The heart action should be monitored during these injections, and administration of the drug should be discontinued as soon as the tachycardia is terminated. Quinidine can be given by the intramuscular route, using about twice the above dose and repeating this dose, if necessary, at hourly intervals.

Procaine amide (Procaine amide hydrochloride, *Pronestyl*) has occasionally proved superior to quinidine, even though it has basically the same mode of action. As a result, this drug has become the drug of choice in ventricular tachycardia. When special haste is indicated, i e , if the attack lasted more than 12 hr, a fresh myocardial infarct has occurred, or there is severe congestive failure, Pronestyl can be given intravenously. Since it has a hypotensive action, this method of administration is *not* recommended if the blood pressure is already very low. In all cases, the injection

3

Extrasystoles

DAVID SCHERF

Extrasystoles are contractions of the whole heart or parts of the heart elicited by the preceding beat and therefore bound to it by a fairly constant interval (*constant coupling*). They are often called *premature contractions*. However, in atrial fibrillation, some of the beats conducted from the atrium are more premature than are the extrasystoles. On the other hand, extrasystoles may not be premature when they appear late in diastole and excite only part of the heart while the rest is excited by the normal impulse. The above definition excludes ectopic extra beats caused by automatism of deeper centers (idioventricular or parasystolic beats). The former come late in diastole, the latter appear in all phases of diastole and therefore do not have a fixed coupling.

HISTORICAL REMARKS

The "skipping of the heart beat," caused by an extrasystole, and the intermittent pulse were known to physicians for many centuries. The Chinese discussed them thousands of years ago. With rare exceptions (see Chinese medicine), this phenomenon was considered to have a bad outlook. Only at the very end of the nineteenth century did Cushny and Wenckebach simultaneously discover that the intermittent pulse is in most cases caused by extrasystoles, for the first time they described correctly this arrhythmia in man.

TYPES

Extrasystoles are divided into different groups depending on the part of the heart from which they originate. While under normal conditions, impulses are formed only in the so-called specialized tissue ("specialized fibers") which alone has automaticity or the ability to form impulses (SA node, AV node, bundle of His, bundle branches and ramifications), under abnormal conditions, extrasystoles may originate in the common muscle fibers. One can elicit extrasystoles from any part of the atria or ventricles by local application of aconitine, digitalis, strophanthin, or hypertonic solutions of sodium chloride and barium chloride. The problem is not definitely solved because it is impossible to decide by histologic methods how far the specialized tissue reaches. It seems, however, improbable that the extrasystoles and atrial tachycardias which appear on application of aconitine on the tip of the left atrium could be caused by firing off of impulses in specialized fibers.

COUPLING

The length of the coupling in a given patient varies little, differences usually amounting only to 0.02 to 0.04 sec. Most often the duration of the coupling is around 0.32 sec, but it may be longer, rarely shorter (0.26 sec). Lewis called the coupling "the forced cycle," as it is ended by the forced beat or extrasystole. The duration of the coupling may be influenced by drugs, such as quinidine, or by the appearance of bundle branch block.

VENTRICULAR EXTRASYSTOLES

These are recognized in the electrocardiogram as premature ventricular complexes, usually of abnormal form. Only rarely do these extrasystoles show a ventricular complex of

sions, being more pronounced and more lasting for attacks of long duration.

Emboli in the greater or lesser circulation can occur after a prolonged attack if a cardiac thrombosis has occurred during the tachycardia.

POSTTACHYCARDIAL SYNDROME

The *posttachycardial syndrome* consists of ECG changes of the ST-T segments which follow paroxysmal tachycardia continued for several days, and which persist from a few days up to 8 weeks. The longer the tachycardia has lasted, the more likely it is for these changes to occur, and the longer they will persist. They consist often of pronounced inversion of the T wave in several leads, which usually makes it possible to localize the disturbance in either the left or the right ventricle. The QRS complex is usually not involved (Fig 11-5B–G). The inverted T wave is generally less pointed than in myocardial infarction, the Q-T interval is prolonged initially. This picture is less common after a supraventricular than after a ventricular tachycardia. This supports the idea that the abnormal T waves reveal damage of that ventricle from which the tachycardia had its origin (Gallavardin, Graybiel and White, Cossio et al.). This phenomenon may occur in otherwise normal cases.

The *symptoms* of the patient are overshadowed by lassitude, especially after a prolonged attack. A transient slight cardiac dilatation has been observed (Cossio et al).

The ECG picture may be considered as evidence of fatigue of the ventricular myocardium resulting from the prolonged tachycardia The metabolism is altered by the uneconomical tachycardia—more altered if the myocardium was damaged before the attack

The *evaluation of the ECG* requires great care, and the following points should be considered:

1. The ECG alterations may be considered evidence of a posttachycardial syndrome only if they were *not* present prior to the attack. Ventricular tachycardia may mask the pattern of an abnormal ECG.

2. If the attack was associated with precordial pain, or if heart failure followed it, one should consider the possibility that there has been a *myocardial infarct.* The clinical data may help in the differential diagnosis, although their absence does not rule out a small infarct. Changes of the QRS complex that were not present before the attack, or the onset of a monophasic wave with elevation of the S-T interval in certain leads, speak for a *fresh myocardial infarct.*

3. If the inversion of the T wave is found chiefly in the chest leads V_1 to V_3, one should consider *acute cor pulmonale* (pulmonary infarct caused by embolism).

4. If the attack was treated with large doses of digitalis glycosides, the typical "digitalis effect" of the ECG is to be expected Quinidine or Pronestyl may cause flattening of the T waves, possibly associated with broader U waves, and occasionally with a prolongation of the QRS complex.

Little is known still about the *pathologic anatomy* of the posttachycardial syndrome. At autopsy of one case, moderate hypertrophy and dilatation of the heart were found, without any other evidence of myocardial lesions (Cossio et al)

In general the *prognosis* is good Even so, occasionally, and without any apparent particular reason, a fatality may occur during an attack.

The abnormal *metabolic* state of the heart requires physical rest and good nutrition Since the nature of this metabolic disturbance has not been clarified, more definite therapeutic measures cannot be used However, adequate supply of glucose, potassium, vitamins, and possibly metabolic enzymes is indicated; there is no indication for cardiac glycosides.

normal systole (Fig. 11-7G). The next normal beat following the extrasystole is not disturbed and comes at the exact moment it would have come had there been no extrasystole (*compensatory pause*).

An interesting phenomenon has been seen in diseased hearts: the T wave of the first postextrasystolic beat may be abnormal, becoming flat or even inverted, particularly in leads V_3 or V_4

Under abnormal conditions, particularly in elderly patients, the first postextrasystolic beat is an "escaped" idioventricular beat from a deeper ventricular center (Figs. 11-7B, 11-9B).

If every beat of the basic rhythm is followed by an extrasystole, there is a *bigeminal rhythm;* if two extrasystoles follow each normal beat, a *trigeminy* is present A succession of many extrasystoles (Fig 11-7D, E) may also be called a *paroxysmal tachycardia.*

Even if extrasystoles continue to occur for many years, they show in the most minute detail the same electrocardiographic pattern, as long as the heart remains healthy and they originate in the same focus If the extrasystoles are *polifocal* or *multiform* (Fig 11-7C, D and 11-9B), they are definitely significant They originate in several foci and spread over the heart in different patterns When several centers exist, one may conclude that several abnormally functioning fibers are present, therefore, *multiform extrasystoles indicate heart disease* They are seen in the different forms of *myocarditis* and most frequently in coronary heart disease (Fig 11-9B)

One should be aware, however, that extrasystoles may be the consequence of *digitalis* action, regardless of how small a dose the patient may be getting They may appear even after a single dose of 0 3 Gm standardized powdered leaves of digitalis After digitalis is discontinued, they may persist for 2 to 3 weeks On the other hand, they were absent in several instances of suicide with digitalis Experimental and clinical data indicate that they appear in digitalized hearts that are exhausted or damaged and *in which the potassium content of the muscle is diminished* The appearance of multiform ventricular extrasystoles during the administration of digitalis is a phenomenon of great importance, as most of these patients develop more and more extrasystoles if digitalis is continued, ultimately, ventricular tachycardia may appear with alternating or continuously changing ventricular complexes Such tachycardias may also appear spontaneously in patients with damaged myocardium (Fig 11-7E).

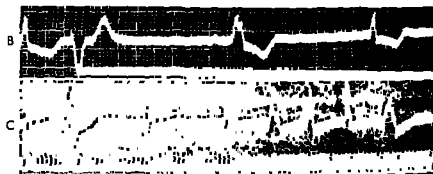
ATRIAL EXTRASYSTOLES

Extrasystoles originating in the atria are recognized in the electrocardiogram by the appearance of *premature P waves* which, in most instances, have a different form than in the existing sinus beats They may be inverted, higher or shorter, differently slurred, or notched. Because of their prematurity, these P waves are often hidden in the preceding T waves and may be recognized only by the change of form of the T waves. In continuous bigeminy, every T wave contains a P wave, so that there is no possibility of comparing them with normally shaped T waves; the diagnosis is then difficult (Fig. 11-8B). Too often, in the absence of a clear P wave, the diagnosis of an AV extrasystole is made and it is presumed that the atrium and ventricle contract simultaneously. Atrial extrasystoles on their way down to the ventricles may find the path blocked by refractory tissue from the preceding systole, and therefore will not be followed by a ventricular contraction. These are called *blocked atrial extrasystoles* (Fig. 11-8C); often, for the same reason, the spread of the atrial extrasystole is abnormal within the ventricles (*aberrant atrial extrasystoles*). This happens even in healthy hearts and has no special significance (Fig. 11-8C). Atrial extrasystoles are followed by *a pause which usually is noncompensatory*

If atrial extrasystoles are *multiform*, atrial fibrillation usually follows, such abnormalities are often seen in the elderly patient and are an indication for therapy with quinidine

EXTRASYSTOLES FROM THE BUNDLE OF HIS

These extrasystoles are rare (Fig 11-7A). They are characterized by premature ventricular contractions showing the same ventricular complexes as the existing sinus rhythm.



SINOATRIAL NODE EXTRASYSTOLES

These extrasystoles are also rare, but they have been studied experimentally and a few typical instances have been observed in man. They are characterized by *premature P waves* exhibiting the same form as the P waves of

the same form as the normal complexes; this is the case only when they originate in the bundle, above the bifurcation (Fig. 11-7A). In most instances the QRS complexes and T waves are abnormal, because *the stimulus originates* in one of the *ventricles* and consequently spreads abnormally. The QRS complexes may be widened, slurred, and notched; the T waves are often oppositely directed (Fig. 11-7B, D) Sometimes, particularly when the basic rhythm is slow, an extrasystole is sandwiched between two sinus beats without disturbing the existing rhythm; this is called an *interpolated extrasystole* (Fig 11-7F). Usually, however, at some time during the extrasystolic contraction, the next normal atrial contraction occurs but cannot be conducted to the ventricles because of the refractoriness caused by the extrasystolic contraction. Thus an extrasystole replaces, so to speak, a

Fig. 11-7. A. Lead III. Prolonged P-R interval in a patient with left bundle branch block; a ventricular extrasystole arises above the bifurcation of the AV conduction system. B. Lead III. Atrial fibrillation, digitalis effect, and ventricular extrasystole, followed by an ectopic, idioventricular, automatic beat. C. Lead III. Atrial fibrillation with multiform ventricular extrasystoles. D. Lead III. Complete AV block; an automatic beat is followed by a series of ventricular extrasystoles which are multiform. E. Lead III. Groups of ventricular extrasystoles with alternation of form. No digitalis had been given. In the vast majority of the cases, such an arrhythmia is the consequence of administration of digitalis. F. Lead III. Interpolated ventricular extrasystole in a patient with posterior infarction. G. Lead I Ventricular extrasystole. The normal P wave is visible between the QRS complex and the T wave of the extrasys

are excited simultaneously, in this case the P wave is hidden in the QRS complex. In another form, the premature P wave precedes the QRS complex by an interval which is *shorter* than the normal P-R interval of the patient. These P waves are very low and positive in lead I, peaked, of short duration, and deeply inverted in leads II and III; they are positive in aVR and inverted in aVF In a third form, the abnormal P wave appears after the QRS complex, usually between the QRS complex and the T wave (Fig. 11-8A).

With certain, well-studied exceptions, the first-named form originates *in the middle part* of the AV node, the next one *in the upper (atrial) part*, and the last one in the *lower (ventricular) portion* It seems that premature inverted P waves with a normal P-R interval may originate in the so-called *coronary sinus node*, an extension of the AV node to the orifice of the coronary sinus For one or several beats following atrial extrasystoles, the P waves of the regular rhythm may show an abnormal form (Fig 11-8D); there is so far no satisfactory explanation for this phenomenon, which is not rare

RETURN EXTRASYSTOLES

These rare extrasystoles may be subdivided into several forms One of them has been well analyzed experimentally but has not been observed in clinical cases. If ventricular extrasystoles are initiated by any method in the dog, they often are conducted backwards into the atria (*retrograde conduction*) If the last of a series of extrasystoles reaches the atria, it is followed by a beat of normal form, and analysis shows that the extrasystolic impulse, while on its way to the atria, has *returned to the ventricles* In another form of the same phenomenon also observed in man, *return extrasystoles* are seen in the type of AV rhythm in which the P wave is present between the QRS complex and the T wave Thus in Fig 11-8E, obtained in an experiment in a dog, all beats with such P waves are followed by a return extrasystole Since one cannot assume that the part of the AV system above the bifurcation which had just conducted the impulse to the atria is able to conduct it immediately down again to the ventricles, one must assume a longitudinal dissociation of the AV system permitting retrograde conduction in one part, normal conduction in another.

EXTRASYSTOLES DUE TO DRUGS AND DIFFERENT COMPOUNDS

Extrasystoles are frequently the consequence of drug action. They may appear sometimes in dangerous numbers and may lead to fatal ventricular fibrillation The most important compounds are listed below.

Digitalis extrasystoles have been mentioned above; it may be stressed again that in the healthy person and in most patients with abnormal hearts such extrasystoles do not appear even after administration of large doses. They appear in experimental animals only before death but are easily elicited if digitalis or strophanthin is applied locally to the cardiac surface (Fig. 11-9A). They are particularly common in the hypertrophied and dilated hearts of rheumatic mitral lesions or coronary sclerosis; investigations have demonstrated a diminished content of potassium in the muscle fibers of these hearts.

Digitalis extrasystoles frequently show differences of form, which may be only slight or very marked.

Quinine, quinidine, and Pronestyl are known to elicit extrasystoles and dangerous tachycardias, as well as fibrillation, in man and in the experimental animal. Their use in combination with certain anesthetics is dangerous

Chloroform and cyclopropane both cause extrasystoles of varying form. The appearance of extrasystoles in anesthesia with cyclopropane is less dangerous than with chloroform. Why cyclopropane occasionally leads to so many extrasystoles and why they do not occur in other cases, is unknown *Trichloroethylene* has a similar action

Epinephrine, caffeine, and *nicotine* often elicit extrasystoles.

CLINICAL DATA

Incidence. Extrasystoles are common in the healthy person. They appear so often that the statement has been made that no adult escapes them permanently. In most people, they are asymptomatic. Extrasystoles appear in all ages and have been often heard on auscultation of the fetal heart. It is not decided as yet whether atrial or ventricular extrasystoles are more common, but in early youth, the atrial type seems to predominate.

Different statistics compiled on different material (hospital patients, patients with heart

the existing sinus beats; often, but not invariably, they are followed by a pause which is *shorter* than that necessary to create a normal P-R interval. The rarity of these extrasystoles and of those from the bundle of His and the AV node is understandable if the following law is considered: centers with highly developed automaticity, i.e., with the ability to form impulses, rarely show abnormal beats of the extrasystolic type; however, centers in the peripheral ramification of the nodes or in the Purkinje system more often exhibit their abnormal extrasystolic impulses.

ATRIOVENTRICULAR (NODAL) EXTRASYSTOLES

These extrasystoles may be divided into three groups. In one, the atria and ventricles

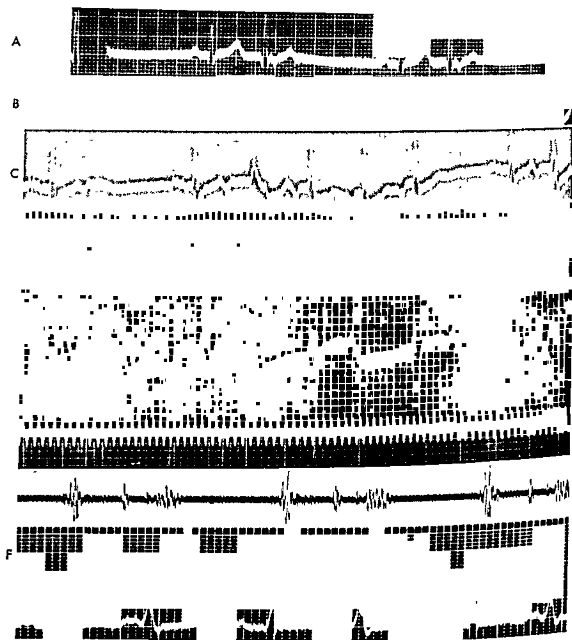

Fig. 11-8. A Lead I. *Nodal or ventricular (?) extrasystoles* with retrograde conduction to the atria, with an inverted P wave between the QRS complex and the T wave B *Atrial extrasystoles in bigeminal groups* with alternation of duration of coupling, and aberration of the QRS complexes of those extrasystoles which have a shorter coupling C. *Blocked atrial extrasystole* at the beginning of the tracing; later, four extrasystoles, with the first conducted to the ventricles with delay and aberration. D *Atrial extrasystoles* with abnormal P wave of the first postextrasystolic beat. E. *AV rhythm* in a dog; lead III. All those beats with an inverted P wave between QRS complex and T wave are followed by a *return extrasystole*. F. Phonocardiogram and lead II of a patient with *bigeminy*. The extrasystole creates only a 1st sound; the 2d sound of the extrasystolic beat is absent.

are excited simultaneously, in this case the P wave is hidden in the QRS complex. In another form, the premature P wave precedes *the QRS* complex by an *interval* which is *shorter* than the normal P-R interval of the patient. These P waves are very low and positive in lead I; peaked, of short duration, and deeply inverted in leads II and III, they are *positive* in aVR and inverted in aVF. In a third form, the abnormal P wave appears after the QRS complex, usually between the QRS complex and the T wave (Fig. 11-8A).

With certain, well-studied exceptions, the first-named form originates in *the middle part* of the AV node, the next one in *the upper (atrial) part*, and the last one in the *lower (ventricular) portion* It seems that premature inverted P waves with a normal P-R interval may originate in the so-called *coronary sinus node*, an extension of the AV node to the orifice of the coronary sinus For one or several beats following atrial extrasystoles, the P waves of the *regular rhythm may show an* abnormal form (Fig. 11-8D), there is *so* far no satisfactory explanation for this phenomenon, *which is not rare.*

RETURN EXTRASYSTOLES

These rare extrasystoles may be subdivided into several *forms. One of them* has been well analyzed experimentally but has not been observed in clinical cases If ventricular extrasystoles are initiated by any method in the dog, they often are conducted *backwards into the* atria (*retrograde conduction*). If the last of a series of extrasystoles reaches the atria, it is followed by a beat *of normal* form, and analysis shows that the extrasystolic impulse, while *on its* way to the atria, has *returned to the ventricles. In another* form of the same phenomenon also observed in *man, return extrasystoles* are seen in the type of AV rhythm in which the P wave is present between the QRS complex and the T wave Thus in Fig 11-8E, *obtained* in an experiment in a dog, all beats with such P waves are followed by a return extrasystole Since *one cannot* assume that *the* part of the AV system *above* the bifurcation which had just conducted the impulse to the atria is able *to conduct* it immediately *down* again to the ventricles, *one must* assume a longitudinal dissociation of the AV system permitting retrograde conduction in one part, *normal* conduction in another.

EXTRASYSTOLES DUE TO DRUGS AND DIFFERENT COMPOUNDS

Extrasystoles are frequently the consequence of drug action. They may appear some*times* in dangerous numbers and may lead to fatal *ventricular fibrillation*. The *most important compounds* are listed below.

Digitalis extrasystoles have been mentioned above, it may be stressed again that in *the* healthy person and in most patients with ab*normal* hearts such extrasystoles *do not appear* even after administration of large doses. They appear in experimental animals only before death but are easily elicited if *digitalis or strophanthin is applied* locally to the cardiac surface (Fig. 11-9A). They are particularly common in the hypertrophied and dilated hearts of rheumatic mitral lesions or coronary sclerosis, *investigations have demonstrated a* diminished content of potassium *in the muscle* fibers of these hearts.

Digitalis extrasystoles *frequently* show differences of *form, which may* be only slight or very marked

Quinine, quinidine, and Pronestyl are known to elicit extrasystoles and dangerous tachycardias, *as well as fibrillation, in* man and in the experimental *animal. Their use in com*bination with certain anesthetics is dangerous.

Chloroform and cyclopropane both cause extrasystoles of *varying form.* The appearance of extrasystoles in anesthesia with cyclopropane is less dangerous than with chloroform Why *cyclopropane* occasionally leads to so many extrasystoles *and why they* do not occur in other cases, is unknown *Trichloroethylene* has a similar action.

Epinephrine, caffeine, and *nicotine* often elicit extrasystoles.

CLINICAL DATA

Incidence. Extrasystoles are common in the healthy person. They appear so often that *the statement* has been made that no adult *escapes* them permanently In most ...

...ation of the fetal heart. It is *not* decided as yet whether *atrial* or ventricular *extrasystoles* are more common, *but in* early youth, the *atrial type* seems to *predominate.*

Different *statistics* compiled on *different* material (*hospital* patients, patients with heart

disease, patients in private practice) show an incidence of 1.5 to 3 8 per cent.

Factors and Diseases Eliciting Extrasystoles. Extrasystoles may appear *after exercise*. In the majority of such instances, the extrasystoles indicate the presence of myocardial or coronary disease. Actually, the appearance of extrasystoles (usually of varying shape) following exercise should arouse the suspicion of *coronary sclerosis*. Extrasystoles after exercise have been seen in *myocarditis*, and in diphtheria.

Extrasystoles are influenced by *posture*. They are more often found in the supine patient or may be seen only if a patient lies on the left or right side.

They appear in some patients during constipation, menstruation, pregnancy, or with meteorism, in others, after smoking or on sexual excitement. Extrasystoles are common in acute myocardial infarction and in cardiac aneurysms In the former, they seem to originate in the area of reactive inflammation surrounding the infarction. They require therapy with quinidine because of the danger of fibrillation. While extrasystoles are common in diphtheritic myocardial necrosis, they occur less frequently in active rheumatic fever, in spite of the frequent involvement of the myocardium, including the specialized tissue.

Extrasystoles are common in the preexcitation syndrome and in a variety of allergic conditions. They are rare in hyperthyroidism in spite of the frequent occurrence of fibrillation.

Symptoms. As mentioned above, symptoms are present only in a small minority of individuals with extrasystoles, but in some unfortunate ones, the symptoms may be distressing.

Many patients complain of *palpitation*. Only further questioning reveals that this sensation consists in a sudden jumping, skipping, or somersault of the heart, and is not continuous but may repeat itself several times per minute. Interpolated extrasystoles may be more dis-

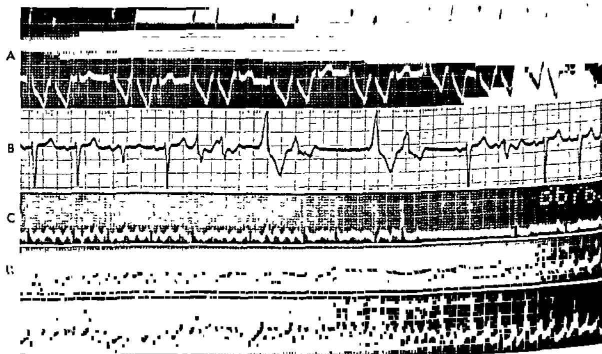

Fig. 11-9. A Lead III in a dog *Trigeminy and multiple extrasystoles* created by focal application of digitoxin to the conus of the right ventricle. B Lead III *Multiple and multiform ventricular extrasystoles and abnormal automatic ectopic beats* in a 72-year-old patient who had received digitalis C. End of an attack of *atrial fibrillation* in a 65-year-old man D Dog, lead II *Atrial flutter* elicited by focal application of aconitine on the tip of the appendix of the right atrium. Cooling of the area of application abolished the flutter and made the sinus rhythm reappear. Discontinuation of the cooling led to reappearance of flutter These results, readily reproduced and confirmed, could not be explained if a circus movement were present. E *Atrial flutter*, elicited in a dog by application of aconitine, is transformed into fibrillation whenever the right appendix is stretched.

tressing than the usual ones It is typical for these sensations to come mostly at rest, which is the time extrasystoles most often occur, chiefly on account of slower rate.

Other patients complain of *dizziness or even of fainting* Questioning elicits that this dizziness lasts only "a second" The reason for the vertigo in the absence of a long cardiac standstill is not known

Pain is a not infrequent complaint It may be "knifelike" or stabbing, and its brevity alone speaks against coronary involvement. Often it is not the *extrasystole itself which* causes palpitation or pain but the first postextrasystolic beat with its larger stroke volume.

Some patients with extrasystoles have a most interesting *cough reflex*. The cough appears simultaneously with the extrasystoles, comes from "nowhere," and may be very annoying The mechanism is not clear, but the *presence of a reflex from the heart or the* pressoreceptors to the respiratory *tract is obvious*

All these sensations are aggravated if the patient feels his pulse and finds it intermittent

Signs. Most extrasystoles are diagnosed by auscultation; the heart tones of the premature contraction followed by a pause are heard However, without an electrocardiogram mistakes, although rare, can occur, since dissociation with interference, parasystole, or even a periodically dropped beat may lead to a similar auscultatory impression The 1st sound of the extrasystolic contraction is often accentuated, the 2d sound may be absent (Fig 11-8F)

The pulse "skips," as it does in periodically dropped beats, in bigeminy, the extrasystoles may be so premature that their pulse waves are not transmitted to the periphery because of the small output this is the "pseudobradycardia" of our forefathers

Extrasystoles may also give the impression of a gallop rhythm, since the two sounds of the beat preceding the extrasystole are occasionally followed by the only sound produced by the extrasystole

PROGNOSIS

t

r

…n over a period of years, they do not lead to complications and can be ignored On the other hand, extrasystoles can elicit fibrillation and, if the ventricles are involved, *sudden death. This happens when extrasystoles occur extremely early, during the last few hundredths of a second* of the T wave of the preceding beat (Fig. 11-12C). If a premature impulse reaches the heart during this phase, the so-called *critical or vulnerable phase*, it leads to rapid firing of impulses resulting in multiple extrasystoles, flutter, or fibrillation. *This does not happen under normal conditions but occurs when the heart is in an "abnormal metabolic" state, for instance when there is abnormal excitability* of a center because of lack of potassium or calcium This is why extrasystoles during chloroform anesthesia and those in acute myocardial infarctions bring so great a potential risk.

THERAPY

When extrasystoles appear, a thorough examination is indicated. If the patient is not aware of the existence of the arrhythmia, it is best not to mention it If he becomes aware of it, he is often disturbed, since for the layman an irregularity of the pulse seems to herald the threat of a cardiac catastrophe. Reassurance and explanation of the phenomenon may help *in many cases It may* be of value to point out to the patient that *no restriction of* activity is required and that he may lead a normal life

The treatment with drugs is reserved for those patients discussed above in whom the extrasystoles create some risk and for those who complain that the arrhythmia disturbs them The *treatment of choice* is *quinidine*, which is given three to six times daily in the form of tablets containing 0 2 Gm, after a test dose of 0 2 Gm Most extrasystoles, but by far not all, disappear with this medication If hypersensitivity prevents the use of quinidine, *one may use Pronestyl*, 0 75 Gm (three capsules), three *to four* times daily While ventricular extrasystoles *respond* well, the atrial type is less frequently influenced

The administration of 4 to 8 Gm daily of *potassium chloride* helps, particularly in digitalis-induced extrasystoles, but this therapy is to be used only if renal function is normal, because it carries the danger of other disturbing arrhythmias. Digitalis therapy often abolishes extrasystoles not caused by this medica-

disease, patients in private practice) show an incidence of 1.5 to 3.8 per cent.

Factors and Diseases Eliciting Extrasystoles. Extrasystoles may appear *after exercise.* In the majority of such instances, the extrasystoles indicate the presence of myocardial or coronary disease. Actually, the appearance of extrasystoles (usually of varying shape) following exercise should arouse the suspicion of *coronary sclerosis.* Extrasystoles after exercise have been seen in *myocarditis,* and in diphtheria.

Extrasystoles are influenced by *posture.* They are more often found in the supine patient or may be seen only if a patient lies on the left or right side.

They appear in some patients during constipation, menstruation, pregnancy, or with meteorism, in others, after smoking or on sexual excitement Extrasystoles are common in acute myocardial infarction and in cardiac aneurysms In the former, they seem to originate in the area of reactive inflammation surrounding the infarction. They require therapy with quinidine because of the danger of fibrillation. While extrasystoles are common in diphtheritic myocardial necrosis, they occur less frequently in active rheumatic fever, in spite of the frequent involvement of the myocardium, including the specialized tissue

tressing than the usual ones. It is typical for these sensations to come mostly at rest, which is the time *extrasystoles most often* occur, *chiefly on* account of slower rate.

Other patients complain of dizziness or even of *fainting*. Questioning elicits that this dizziness lasts only "a second." The reason for the vertigo in the absence of a long cardiac standstill is not known

Pain is a not infrequent complaint. It may be "knifelike" or stabbing, and its brevity alone speaks against coronary involvement. Often it is not the extrasystole itself which causes palpitation or pain but the first postextrasystolic beat with its larger stroke volume.

Some patients with extrasystoles have a most interesting *cough reflex* The cough appears *simultaneously with the* extrasystoles, comes from "nowhere," and may be very annoying The mechanism is not clear, but the presence of a reflex from the heart or the pressoreceptors to the respiratory tract is obvious

All these sensations are aggravated if the patient feels his pulse and finds it intermittent.

Signs. Most extrasystoles are diagnosed by auscultation; the heart tones of the premature contraction followed by a pause are heard. However, without an electrocardiogram, mistakes, although rare, can occur, since dissociation with interference, parasystole, or even a periodically dropped beat may lead to a similar auscultatory impression. The 1st sound of the extrasystolic contraction is often accentuated, the 2d sound may be absent (Fig 11-8F)

The pulse "skips," as it does in periodically dropped beats, in bigeminy, the extrasystoles may be *so premature that* their pulse waves are not transmitted to the periphery because of the small output: this is the "pseudobradycardia" of our forefathers

Extrasystoles may also give the impression of a gallop rhythm, since the two sounds of the beat preceding the extrasystole are occasionally followed by the only sound produced by the extrasystole

PROGNOSIS

The vast majority of extrasystoles represent a harmless phenomenon Whether they appear singly or in series, occasionally or continuously, even over a period of years, they do not lead to complications and can be ignored. On the *other* hand, extrasystoles can elicit fibrillation and, if the ventricles are involved, sudden death. This happens when extrasystoles occur extremely early, during the last few hundredths of a second of the T wave of the preceding beat (Fig. 11-12C). If a premature impulse reaches the heart during this phase, the so-called *critical or vulnerable phase*, it leads to rapid firing of impulses resulting in multiple extrasystoles, flutter, or fibrillation. *This does* not happen under normal conditions but occurs when the heart is in an "abnormal metabolic" state, for instance when there is abnormal excitability of a center because of lack of potassium or calcium This is why extrasystoles during *chloroform anesthesia and those in acute myocardial infarctions bring so great a* potential risk.

THERAPY

When extrasystoles appear, a thorough examination is indicated. If the patient is not aware of the existence of the arrhythmia, it is best *not to mention it. If* he becomes aware of *it, he as often disturbed, since for the layman an irregularity* of the pulse seems to herald the threat of a cardiac catastrophe. Reassurance and explanation of the phenomenon may help in many cases It may *be of value to* point out to the patient that no restriction of activity is required and that he may lead a normal life

The *treatment with drugs is reserved for* those patients discussed above *in whom the* extrasystoles create some risk and for those who complain that the arrhythmia disturbs them The treatment of choice is *quinidine*, which is given three to six times daily in the form of tablets containing 0.2 Gm, after a test dose *of* 0 2 Gm. Most extrasystoles, but by far not all, disappear with this medication. If hypersensitivity prevents the use of *quinidine*, one may use *Pronestyl*, 0 75 Gm (three capsules), three to four times daily. While ventricular extrasystoles respond well, the atrial type is less frequently influenced.

The administration of 4 to 8 Gm daily of *potassium chloride helps*, particularly in digitalis-induced extrasystoles, *but this* therapy is to be used only if renal function *is normal*, because it carries the danger of other disturbing arrhythmias Digitalis therapy often abolishes extrasystoles not caused by this medica-

tion, but one would not give digitalis for such a harmless phenomenon.

MECHANISM

The mode of origin of extrasystoles is known only for the "return" extrasystoles, where one may assume that the impulse conducted in a retrograde way from the ventricles or the AV node to the atria *returns* and "reenters" the ventricles. For the others, the mechanism remains unknown.

There are two main theories. They have in common the assumption that the beat preceding the extrasystole elicits it. The constant coupling of the extrasystoles and the many experiments showing that they disappear when the eliciting beat is inhibited by vagal stimulation prove this assumption to be correct.

One theory, which exists in numerous modifications, assumes *a reentry movement;* it is believed that the impulse, while spreading over the heart, is conducted in a penultimate twig of the conduction system only in one direction with some delay, and that the conduction path is then reentered, thus a second impulse, the extrasystole, spreads over the heart. It must be conceded that these theories are purely theoretical and are not based on experimental facts or clinical observations. There is only one experimental finding, by Schmitt and Erlanger, which is often quoted in support of this theory. The authors believed they had shown that in a small muscle strip, an impulse starting at one end reached the other and then returned to the initial point The authors assumed that the impulse was conducted only in one part of the cross section of the strip (from A to B) so that it could return to A via another pathway. Experiments by Arvanitaki and Bozler have, however, shown that this assumption is incorrect. The impulse traveling from A to B may elicit in one cell at B a repeated firing of impulses and, when a cell becomes depolarized more than once, the second depolarization may spread again over the muscle strip and reach A.

This leads to a second explanation which the author favors· that the *extrasystoles are due to the repeated firing off of impulses.* Normally, when an impulse spreads over the heart, every cell is depolarized once When, because of prolonged negative afterpotential, loss of calcium, or other abnormalities, one cell becomes depolarized *twice* (afterdischarge), a bigeminy appears, since the second depolarization, appearing after the refractory phase of the heart, may form a propagated impulse. A similar phenomenon has been demonstrated for various types of nerves, and its occurrence was proved in the heart muscle of experimental animals If a long series of depolarizations follows (*repetitive response*), the patient has one of several forms of paroxysmal or ectopic tachycardia.

4

Flutter and fibrillation

DAVID SCHERF

ATRIAL FORM

Definitions. In atrial flutter, the atrium contracts 200 to 400 times per minute, the movements are coordinated and are named after the rapid movements of the wings of certain birds (Fig. 11-9D). In atrial fibrillation, the impulses formed in the heart are more rapid, so that as they spread over the atria, they meet refractory tissue and coordinated contraction ceases (Fig. 11-9C). A fibrillating atrium gives the impression of the rippling seen when a gentle evening breeze agitates the surface of a lake. Occasionally the atrial contractions are slightly irregular, so that they cannot be called flutter, while they are not sufficiently irregular for fibrillation. A status of *impure flutter* or *flutter-fibrillation* is then said to exist.

BRIEF HISTORICAL REMARKS

Fibrillation was first elicited experimentally over 150 years ago, but the "pulsus irregularis perpetuus," the "delirium cordis," was known for a long time to occur in man. That atrial fibrillation is responsible for this common clinical phenomenon was proved for the first time simultaneously by Rothberger and Winterberg (1909) and by Sir Thomas Lewis (1909). Flutter was observed and so named by Williams (1887) but described in man by Jollie and Ritchie (1910).

THE ELECTROCARDIOGRAM

The electrocardiographic picture is easily recognized in atrial fibrillation. Instead of normal P waves preceding the QRS complexes, irregularly formed fibrillation waves (F waves), with a rate up to 600, are present. They continuously vary in form and rate (Fig. 11-9C). The ventricular activity is completely irregular, except in those patients who also have complete AV block. The F waves are sometimes coarse, sometimes fine, and may even be invisible in most leads, with the exception of V_1 and V_2. However, the absence of P waves and the complete irregularity of the heart make the diagnosis possible in the last case.

In atrial flutter, the P waves or F waves are regular in form (Fig. 11-10B). They follow each other like the regular teeth of a saw with continuous motion, but short isoelectric lines may separate one F wave from another (Fig. 11-9D). It should be stressed that the form of the F waves alone differentiates flutter from fibrillation: these waves are regular in flutter and irregular in fibrillation (Fig. 11-11).

The ventricular rate and rhythm in flutter show all possible variations. The ventricles may beat rapidly and regularly at a rate greater than 300 per minute when every atrial impulse is conducted to the ventricles (*flutter with full rhythm*). If an intraventricular conduction disturbance coexists or if, because of the rapid rate, the intraventricular conduction is aberrant, a picture similar to that of a ventricular tachycardia appears in the electrocardiogram (Fig. 11-10F). More often the arrhythmia is confused with an atrial paroxysmal tachycardia (Fig. 11-10C). However, in the majority of cases, the AV conduction system is able to conduct only every second, third, or fourth atrial impulse to the ventricles, so that a 2:1, a 3:1, or 4:1 block appears (Fig. 11-10B). If the blocking is irregular, the ven-

tricles may show the same *complete arrhythmia* as in fibrillation. If there are 4:1 and 2:1 blocks alternating regularly, a *bigeminal rhythm* caused by extrasystoles may be diagnosed on auscultation.

CLINICAL DIAGNOSIS

This is easy in *fibrillation* because of the complete irregularity of the heart. Confusion with irregularly placed extrasystoles may occur and is fatal if the series of irregularly grouped ventricular extrasystoles seen in digitalis intoxication is confused with atrial fibrillation with a rapid ventricular rate, and if the physician, without the help of an ECG, decides that the patient needs more digitalis. In doubtful cases one may be aided by the knowledge that extrasystoles usually disappear after exercise or the inhalation of amyl nitrite while the irregularity of fibrillation increases with these measures

The clinical diagnosis of *atrial flutter* is possible in most instances. A fundamental clinical rule should be that every regular heart activity with a rate of 100 to 160 per minute should arouse suspicion of flutter with 2:1 or 3:1 block. In sinus tachycardia, the rate increases with the patient standing or performing moderate exercise, and gradually returns to its former level with rest. In flutter, as well as in the paroxysmal tachycardias, the rate remains the same. However, more strenuous exercise causes change of block, so that a 3:1 block changes into a 2:1, or the latter into full rhythm, there are characteristic mathematic relations between the rate prior to and after

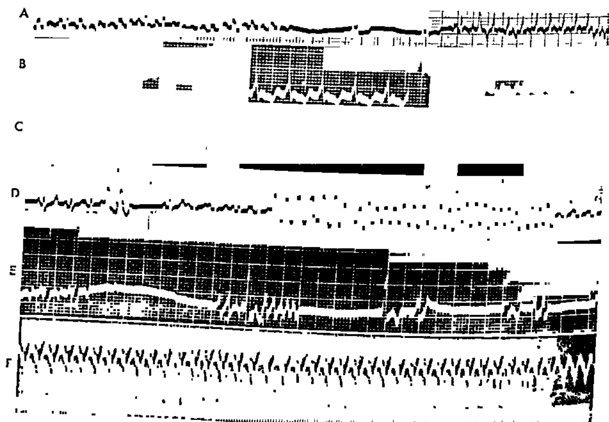

Fig. 11-10. A *Atrial flutter*, caused in a dog by focal application of aconitine, is immediately abolished by cooling the area of application Two sinus beats appear. Discontinuation of the cooling leads immediately to atrial fibrillation B The three standard leads. *Atrial flutter* with 2 1 block. the exercise. The original rate is suddenly restored after a few minutes Carotid pressure or any other vagal reflex stops a paroxysmal tachycardia for a longer or shorter time but affects the rate in flutter or sinus tachycardia only while pressure is exerted.

Whether it is permissible to differentiate atrial flutter from paroxysmal tachycardia has been questioned, particularly since rapid firing of impulses is considered to be the responsible mechanism in both conditions *The author believes that these conditions should be separated in spite of certain similarities.* In paroxysmal tachycardias, carotid pressure often abolishes the tachycardia In flutter, this does not happen and actually vagus stimulation increases the flutter rate and causes fibrillation (Fig 11-12B) Many drugs which are effective in abolishing atrial tachycardias are useless in flutter. Atrial flutter is common in cardiac patients and rare in otherwise apparently healthy individuals; the situation is reversed for paroxysmal tachycardias Flutter often changes, spontaneously or after digitalis administration, into fibrillation This is extremely rare in a paroxysmal tachycardia.

CLINICAL CONSEQUENCES

The *ventricular rate* alone is of importance in these abnormal rhythms If with a higher degree of block, the rate is around 80, the patient has an almost normal circulation and may not even notice the restoration of normal rhythm With a rate of about 120, the patient will be handicapped, particularly on undertaking physical exertion With higher rates, cardiac failure, with high venous pressure, hepatic enlargement, fall of the arterial pressure, and cardiac enlargement, will result in direct relation to the rate.

OCCURRENCE

Atrial fibrillation (a more common event) and atrial flutter may occur in apparently healthy people. They may be observed for decades or even during a lifetime without other evidence of cardiac involvement. It is possible that a postinfectious (streptococcic) myocarditis, subclinical and rapidly healed, was originally responsible. We knew one physician who had been refused life insurance because of atrial fibrillation when he was in his twenties; he died at 84, and not from heart disease. The fibrillation never stopped and never required therapy since the ventricular rate remained slow.

In certain lesions, fibrillation is common. It appears sooner or later in most patients with mitral stenosis, hyperthyroidism (which is often masked), or coronary sclerosis. It is rare in cor pulmonale and in many congenital heart lesions. It has been described in healthy young men after severe physical strain. It occurs under certain experimental conditions when the atria are stretched or overfilled (Fig. 11-9E) A high vagus tonus (Fig. 11-12A) and the topical application or intravenous injection of acetylcholine cause flutter or fibrillation (Fig. 11-10E) in the experimental animal. Fibrillation is occasionally seen in a normal dog when the vagus in the neck is stimulated with a faradic current (Fig. 11-12A).

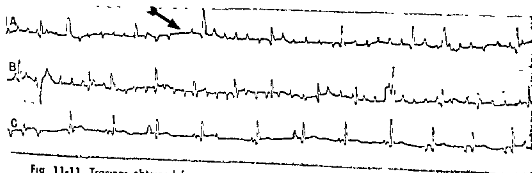

Fig 11-11 Tracings obtained from a patient with shifting of the pacemaker from the SA node to the AV node (C) There is also a change from positive to negative P waves during the presence of flutter This is also explained by two active centers, one in the SA node and one in the AV node, at times, when both centers form impulses simultaneously (arrow in A), an almost isoelectric P wave is obtained.

THERAPY

Fibrillation. It has been stressed that the ventricular rate alone is responsible for the disturbances caused by flutter and fibrillation. Actually, in fibrillation the atria do not contribute to cardiac dynamics as they are practically paralyzed, and with the disappearance of sinus rhythm, venous and atrial pressures rise, even when the ventricular rate during fibrillation was slow. This does not hold true, however, for all patients, and it must be stressed that fibrillation may persist for many decades without the patient's being handicapped in any way, provided the ventricular rate is slow.

The chief therapeutic problem is to slow down the ventricular rate, and this is often accomplished by *digitalis*. This is, however, a purely symptomatic form of therapy Patients respond to it readily unless complications such as hyperthyroidism, active rheumatic fever, or pulmonary embolism exist. Once the ventricular rate is below 80 beats per minute, a maintenance dose will keep it at this level.

Only rarely should an attempt be made to eliminate fibrillation. This is recommended when hyperthyroidism is cured but fibrillation persists; if fibrillation appears during pneumonia or some other infectious disease and does not disappear spontaneously; or when fibrillation has just started in slight mitral stenosis and a loud presystolic murmur indicated earlier that the left atrium still contributed to ventricular filling. In the vast majority of cases defibrillation is not indicated. Several independent investigators have found that *quinidine* therapy causes death in 4 per cent of the cases, even when doses of not more than 1.5 to 2 0 Gm are given daily. The

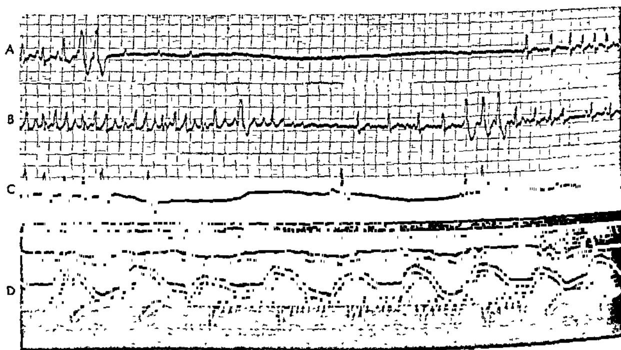

Fig. 11-12. A and B are continuous Lead III, dog experiment. The animal had received veratrine before, and parts of the SA node had been crushed by a clamp. In A, atrial fibrillation appears during faradic stimulation of the right vagus nerve in the neck. When this fibrillation changed into flutter, a repetition of the vagus stimulaton led immediately to fibrillation. Sinus rhythm reappeared on termination of the second vagus stimulation C Dog experiment; veratrine, applied locally to a small area of the outflow tract of the right ventricle, had led to the appearance of ventricular extrasystoles. Cooling of the area of application led to the disappearance of the extrasystoles. There is cardiac standstill, presumably because the rapid extrasystoles were retrogradely conducted to the atria and inhibited the SA node. The first sinus beat is followed by an atrial extrasystole, which, reaching the ventricle during its critical, or vulnerable, phase, elicits ventricular fibrillation. D. Dog experiment. Lead from anus to esophagus. Complete AV block existed after severing both bundle branches The top line represents a signal, the second a mechanogram of the right atrium, and the third a mechanogram of the right ventricle. One short electrical shock (signal) leads to a short attack of atrial fibrillation.

incidence of fatalities increases if larger doses are administered. Patients have *died from ventricular fibrillation or respiratory standstill or* systemic embolism. Thus, the patient is exposed to *a not inconsiderable* danger without too great a benefit. *In most* patients with mitral *stenosis*, *the* dilated left *atrium* fails anyway to *contribute to the dynamics of the circulation*. In any case this therapy should *always be carried* out only in a hospital, for *continuous supervision of the patient is essential*. The *second* chief reason against this therapy *is that, in* most patients (actually in *almost* all of them if they suffer from rheumatic heart disease or coronary sclerosis), fibrillation *reappears and often is again* present within a few days after therapy is discontinued. In order to avoid embolism, it is recommended that an anticoagulant be given for 14 days prior to the quinidine therapy, so that thrombi already *present* will have time to adhere to the wall and no new ones will form.

Experience shows that with any method of administration of *quinidine*, one succeeds in reestablishing sinus rhythm in about 60 per cent of the patients. At first, a test dose of 0.2 Gm is given in order to determine whether there is hypersensitivity. *On the next day*, 0.2 Gm is given every 2 hr from 8 A.M. to 8 P.M., or 0.4 Gm every 4 hr day and night. The success is the same with both procedures. If no result is obtained, the single doses may be increased, but this is recommended only under close supervision, since the risks are increased. In recent years, frequent use of quinidine therapy for interruption of fibrillation has been recommended without good reasons.

Flutter. In this condition, treatment is usually required and is more difficult. It is more often necessary because only exceptionally does the patient with flutter have a slow ventricular rate at rest and with the ordinary exertions of daily life. The rate is usually too high and the circulation deteriorates. The therapy is more difficult, since in most cases the administration of digitalis in the usual dosage does not inhibit AV conduction and cannot thereby slow the ventricular rate. The slower impulses of flutter are less inhibited on their way to the ventricle than the faster impulses of fibrillation.

Since flutter is transformed *into fibrillation by large doses of digitalis*, one can prescribe *from the beginning* about 0.5 mg *digitoxin* daily, and *in most* patients will succeed within *a few days* in transforming the flutter into *fibrillation*. When this is accomplished, the continuous administration of small maintenance doses of digitalis will keep the rate down; sometimes fibrillation changes spontaneously *into sinus rhythm*. *Some* authors prefer to start with *quinidine* at once without using digitalis, the dosage being the same as in *atrial* fibrillation. If quinidine is used in flutter or fibrillation, a paradoxic *phenomenon is common*, viz., an increase of *ventricular rate*. *This* is explained by the atropine-like action of quinidine on the vagus endings, which appears even with the use of ordinary clinical doses. *There* are, *however*, *instances of atrial* flutter *in which digitalis therapy* does not change the existing rhythm, despite the largest tolerated doses, and in which quinidine also fails. In such cases one must abandon treatment and try again after a few months.

VENTRICULAR FLUTTER AND FIBRILLATION

Ventricular flutter has been described repeatedly, but no accepted rules exist on its separation *from* rapid ventricular paroxysmal tachycardia (Fig. 11-10D). As in atrial flutter, the rate may be decisive. It may, in the dog, reach 500 or more.

Ventricular fibrillation is one of the most common causes of sudden death, for the circulation stops (Fig. 11-12C). It *is often survived* in the cat and in small mammals, since in them it stops spontaneously. This happens only rarely in man. It has been seen in complete heart block *in* coronary sclerosis, particularly when quinidine is being given. Ventricular fibrillation is a not uncommon cause for fatal accidents during administration *of anesthesia*, particularly with *refrigeration* of the heart.

Of interest *is* the *ventricular fibrillation* which *appears after prolonged hyperventilation* with resulting hypocapnia. *A rise* in serum potassium and a fall *of potassium in* the heart *muscle seem to be responsible*. Two methods are available *to eliminate it* and to revive a patient with ventricular fibrillation. One is the old method of Prevost and Bacelli, who recommended strong electrical shocks. Through the *efforts of Zoll* (1952), relatively simple de-

vices are now available for this purpose and permit stimulation of the heart even with an unopened chest. The other method is rapid exposure of the heart by a large incision in the fourth intercostal space; intracardiac administration of procaine; massage, and administration of oxygen. The latter is done by intratracheal tube or mouth-to-mouth breathing if no tube is available, for quick action is urgent; the cortical centers are very sensitive to lack of oxygen and are damaged if the circulation is arrested for more than 3 min.

Mechanism of Origin. The mechanism of flutter and fibrillation in the atria or ventricles has long been unknown, but recently additional data have been brought forward favoring one of the existing theories. For more than 65 years flutter and fibrillation were explained by rapid impulse formation in one or several centers in the atria or ventricles respectively. There are many modifications of this theory based on experimental evidence. The centers were located in the SA node, in the AV node, or both. These theories were practically abandoned when the *circus movement* theory was developed, mainly by Lewis (1916) and Garrey. Lewis based his work on previous experiments by Mines and Romanes and assumed that a "circus" or "reentry" wave moves up or down the SA node and follows a circular pathway, from this "mother" or "central" wave, the rest of the heart is excited by centrifugal excitation waves. This fascinating theory was generally accepted, and even in textbooks of physiology it was "the" explanation; in some it still is. This was mainly because of the very elaborate and well-arranged experiments of Lewis, which seemed to be convincing. Objections to his theory were raised many years ago but were disregarded. Thus, Rothberger pointed out (1922) that the two fundamental experiments, one in the dog and one in man, which Lewis considered crucial in proving the existence of a circus movement, were actually open to serious criticism Even the existence of a circular path in this area still lacks anatomic proof, and the use of the whole path by a circus wave has never been demonstrated. If this wave were present, broad ligatures across the path should stop electrically induced flutter, but they do not, as demonstrated by the author (1928).

Lewis himself stressed that his theory cannot explain ventricular fibrillation and that this constituted a serious weakness because of the identity of the atrial and the ventricular form. Ventricular fibrillation was explained by Garrey's hypothesis, which is based on much less experimental data than the theory of Lewis.

Experiments of the author and his coworkers have shown that atrial (Figs. 11-9D and 11-10A) and ventricular flutter and fibrillation (Fig. 11-10A) can be caused by topical application of *aconitine*. Other experiments demonstrated that atrial flutter can, in this way, be caused by rapid impulse formation in one center; that atrial fibrillation can be evoked by rapid impulse formation in one or several centers, that ventricular flutter can originate from rapid firing of impulses in one center. There is no proof of the mechanism of ventricular fibrillation, but the activity of several centers is probable. It is assumed, on the basis of experimental data, that rapid impulse formation in one center induces rapid impulse formation in others, as this relationship has been known for a long time to exist in the nervous system.

Since the existence of at least two forms of fibrillation of the atria causing identical electrocardiographic patterns has been proved, viz., the arrhythmia arising in one or in several centers, other forms may exist. There is, however, no proof that a "circus movement" may be responsible, if it occurs locally, it may well be merely the consequence of rapid impulse formation and the appearance of islands of refractory tissue. If this is the case, it would be maintained by fibrillation but would not sustain it.

Pathologic findings in disturbances of rate or rhythm

ANTONIO COSTA

SINUS BRADYCARDIA

A possible cause of sinus bradycardia is *arteriosclerosis* of the artery which supplies the SA node (Fiorio), followed by fibrosis of the nodal tissue Caution should be taken in the evaluation of the pattern, because similar lesions have been considered responsible for paroxysmal tachycardia (*Doerr*). A *congenital* absence of the SA node has never been observed, *even in malformations* of the superior vena cava Theoretically, this would cause a slow pulse due to nodal rhythm.

ATRIAL FIBRILLATION

It is difficult to find a correlation between atrial fibrillation and atrial lesions of rheumatic, sclerotic, or toxic nature On the contrary, it is more likely that, in accordance with Prinzmetal's concept (1951), there is an ectopic focus, generally in the posterior wall of the right atrium, represented by an area of intact myocardium within the rest of the degenerated tissue

ATRIOVENTRICULAR BLOCK AND BUNDLE BRANCH BLOCK

The *pathologic findings in cases with disturbances* of conduction are by no means concordant According to Bach, Pardee, Laubry, etc , the electrocardiographic pattern of block can be found in patients in whom histologic sections fail to disclose lesions of the conducting bundles This possibility, however, is denied by others (Beretta and Maestrelli), who found alterations in all the cases submitted to study Even in the so-called "functional blocks," structural lesions of the conduction system should be admitted, in addition to functional disturbances (Fig 11-13). Several authors, on the other hand, deny that a localized or diffuse damage of the cardiac muscle can determine a pattern of bundle branch block without simultaneous lesions of the conducting system (Scherf, 1925, Laubry et al., Smith, 1932, Robinson).

Transient or *functional block* is often due to minor lesions of the branches that may escape *even an accurate study On the other hand,* diffuse degenerative or sclerotic lesions of the *AV node and bundle of His have been* described without the occurrence of specific electrocardiographic pattern of block

According to Monckeberg, failure to demonstrate lesions of the bundle of His in typical cases of block may be explained by (1) incomplete histologic examination of the conducting system, (2) lesions of the neurologic components of the bundles, (3) existence of anatomic abnormalities, such as anastomoses between the two branches

The value of a *functional factor* was overestimated in the past but still should not be *altogether disregarded.* A lesion of a small area of the conducting system may become "functionally" total *because of compression* and stretching of the other fibers Serial histologic studies have shown *an interruption of the*

branches in all cases of block clinically diagnosed

The localization of the lesion in cases of bundle branch block has been the object of numerous studies, because for a long time, there was no agreement between the findings and the ECG pattern. In most observations, the alterations involved both branches, even though one of them was generally more injured than the other. However, the reversal of opinion due to the school of Wilson finally reconciled the clinical interpretation with the pathologic findings. On the whole, few cases of bundle branch block have been studied histologically and the technique used is not always above reproach Mahaim (1928) emphasized the need for serial, uninterrupted sections of the bundle of His and its branches. His conclusions were as follows:

1 In bundle branch block, the lesions are usually bilateral, even though one of the branches shows more severe damage

2. The branch with the worst lesions is usually that which had been suspected on the basis of electrocardiography.

3. Right bundle branch block is most often due to a lesion of subdivisions of the anterior descending branch of the left coronary artery.

4 Left bundle branch block, as a rule, is not caused by ischemic factors because of its dual blood supply. It is usually caused by an inflammatory process which spreads from the valves to the septum and from there to the left branch. These conclusions are not completely above criticism but give an idea of the complexity of the problem.

It is interesting to mention that extensive lesions of both branches have been found without typical ECG patterns of bundle branch block (Yater, 1938). This might be explained by the existence of a few intact fibers, still able to conduct the stimulus. Therefore, it shall be concluded that the most important point is the localization of the lesion and not its nature

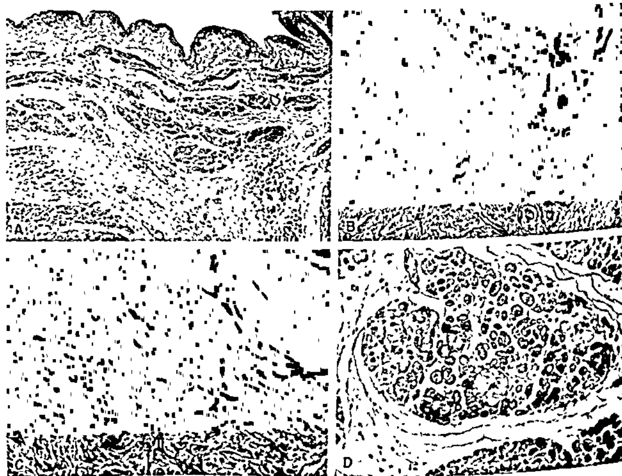

Fig. 11-13. A Rheumatic myocarditis Aschoff nodes near the left branch of the AV bundle. B SA node; moderate hyperplasia of the connective tissue C. SA nodes; severe hyperplasia of the connective tissue. D. Right branch of the bundle of His. degenerative phenomena of the conducting fibers.

Vascular, inflammatory, and degenerative lesions may affect the conducting system either with the rest of the myocardium or as an isolated process (Fig. 11-14). The *vascular changes* are characterized by *small hemorrhagic areas* favored by the rich vascularization, and by areas of degeneration. AV block or bundle branch block has been often observed in the course of a myocardial infarct Mahaim (1928) and Hochrein have described the frequency and causes of this condition

In general, it is admitted that the bundle branch block which appears in cases with coronary arteriosclerosis is due to lesions of either one or both of the branches According to Mahaim, the occlusion of the anterior descending branch causes *right bundle branch block* or *AV block* Actually, the AV node, the bundle of His, and its right branch receive their blood supply from this arterial branch On the contrary, left bundle branch block appears when the right coronary artery is also occluded Many authors (among them Hochrein) have accepted this viewpoint, which is not accepted by Master and coworkers

Among the *inflammatory processes*, acute interstitial myocarditis, rheumatic nodules, and purulent myocarditis have been described Small abscesses of the conduction bundle should be considered as a result of diffusion of the inflammatory processes to the bundle through the endocardium, less often they are caused by a shower of mycotic emboli, as in a case of Mahaim.

AV block is an important complication of diphtheria and reveals the existence of severe myocarditis.

Generally, the AV block, which is frequently observed in *many infectious processes* (pneumonia, scarlet fever, influenza, mumps, rubeola), is not accompanied by specific lesions of the conducting system; the block is likely to be caused chiefly by action of toxins on the AV node and the conducting bundles. Such a toxic-infectious process may explain the AV block observed in the course of *rheumatic fever* and *diphtheria* without focal lesions [1] In some of these cases, albuminoid, hyaline, fatty,

Fig. 11-14. A SA node, hyperplasia of the elastic tissue in the wall of the nodal artery. B. Thickening of the wall of the nodal artery in a patient with pentalogy of Fallot. C. Left branch of the bundle of His, isolated fibers of the conductive system surrounded by thick fibrotic tissue.

waxy, or vacuolar degeneration has been observed

Specific granulomatous processes have been observed in addition to more common inflammatory lesions, these processes were particularly described in cases of *syphilitic* or *tubercular myocarditis*

Syphilis is an uncommon cause of AV block. However, the conduction disturbance may be due to a gumma infiltrating the bundle of His or both branches, to gummatous myocarditis spreading from the aorta, or to an aortitis causing narrowing of the coronary mouths.

In cases of *calcific aortic stenosis*, different

[1] A toxic process may be such as to be inapparent upon routine histologic examination while it might be revealed by more refined studies of histochemistry. *Editor.*

degrees of AV block may be caused by the spreading of the calcific process from the aortic ring to the conduction tissues in the ventricular septum.

Fiorio and Marino studied the alterations of the AV system in *experimental thyrotoxicosis*, and observed degenerative lesions consisting of sclerosis and calcification of the system, with its partial or total interruption. Less frequently were noted atrophic phenomena caused by compression of calcium deposits at the level of the trigoni fibrosi.

Primitive and secondary tumors may cause the interruption of the conducting system (Mahaim, 1928). Nagayo described a primary leiomyoma of the branches, and Monckeberg, a lymphangioendothelioma of the AV node. *Fetal and neonatal fibroelastosis* may cause interruption of the bundle of His and its branches (Mahaim, 1928).

Congenital AV block is considered by Yater and coworkers as due to a septal defect or to a defect in the development of the conductive tissue. Histologic studies have shown in some cases a separation between the AV node and the bundle of His caused by a fibrous nucleus. This lesion is, however, very rare.

In a study on the conducting system in congenital heart diseases, Costa and Fiorio observed that the defects of the septum membranaceum have little importance in regard to the disposition and structure of the adjoining conduction system. Defects of the interventricular septum, on the other hand, are often associated with disturbed growth of the bundle of His resulting in poor development and abnormal course of the left branch.

THE WOLFF-PARKINSON-WHITE SYNDROME

The Wolff-Parkinson-White syndrome is apparently caused by an abnormal and specific lesion in the atrium or near the AV node, the hypothesis of an aberrant bundle has never been documented by serial histologic studies[2] Katz, in one-half the cases with this syndrome, observed the existence of heart disease of either inflammatory (rheumatic, syphilitic, etc.) or degenerative type

The most common pathologic findings are interstitial edema, vacuolar degeneration of the myocardial fibers, chronic rheumatic myocarditis, and scars near the AV node.

[2] Good evidence in favor of an aberrant bundle has been gathered, including histologic studies (Chap 10). *Editor.*

Sinoatrial and atrioventricular blocks

SAMUEL BELLET

SINOATRIAL BLOCK

General Features. In sinoatrial (*SA*) block, there occurs a sudden decrease in the heart rate, usually to almost half the previous normal rate, which may last for one cycle, several cycles, minutes, or hours. This decrease in heart rate can be explained on the basis of an actual physiologic block occurring within or around the structure of the SA node and preventing conduction of the impulse to the atria.

This sudden halving of the heart rate is usually preceded by a slight speeding up of the heart and is followed by cycles which are slightly longer but which then gradually shorten until the usual cycle is reestablished. Both the atria and ventricles participate in the irregularity (Fig. 11-15). The heart rate may be as slow as 30 to 36 beats a minute. This condition should be differentiated from other types of slow heart action, particularly sinus bradycardia and various degrees of AV block.

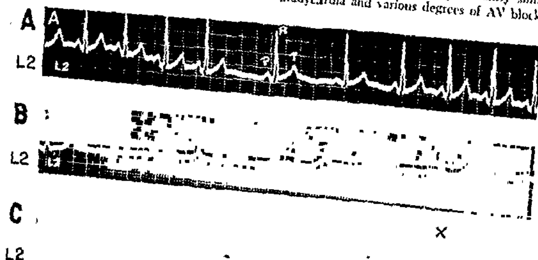

Fig 11-15 A Sinus arrhythmia. Note the phasic variation of the R-R interval. The rate increases during inspiration and becomes slower during expiration. The shorter cycles are associated with a decreased T-P interval. The P-R interval remains constant throughout. B. Sinus bradycardia. Both the atrial and ventricular rates are slow (34 per minute), and the P-R interval is normal. C. Note the presence of a normal sinus rhythm with a rate of 75 per minute. In the last cycle (marked X) a long pause is observed. The cycle length of the long cycle is slightly less than that of two normal cycles. This constitutes a SA block (occasionally the R-R interval of the long cycle is exactly equal to that of two normal cycles).

degrees of AV block may be caused by the spreading of the calcific process from the aortic ring to the conduction tissues in the ventricular septum.

Fiorio and Marino studied the alterations of the AV system in *experimental thyrotoxicosis*, and observed degenerative lesions consisting of sclerosis and calcification of the system, with its partial or total interruption. Less frequently were noted atrophic phenomena caused by compression of calcium deposits at the level of the trigoni fibrosi.

Primitive and secondary tumors may cause the interruption of the conducting system (Mahaim, 1928). Nagayo described a primary leiomyoma of the branches, and Monckeberg, a lymphangioendothelioma of the AV node *Fetal and neonatal fibroelastosis* may cause interruption of the bundle of His and its branches (Mahaim, 1928).

Congenital AV block is considered by Yater and coworkers as due to a septal defect or to a defect in the development of the conductive tissue. Histologic studies have shown in some cases a separation between the AV node and the bundle of His caused by a fibrous nucleus. This lesion is, however, very rare.

In a study on the conducting system in congenital heart diseases, Costa and Fiorio observed that the defects of the septum membranaceum have little importance in regard to the disposition and structure of the adjoining conduction system. Defects of the interventricular septum, on the other hand, are often associated with disturbed growth of the bundle of His resulting in poor development and abnormal course of the left branch.

THE WOLFF-PARKINSON-WHITE SYNDROME

The Wolff-Parkinson-White *syndrome* is apparently caused by an abnormal and specific lesion in the atrium or near the AV node, the hypothesis of an aberrant bundle has never been documented by serial histologic studies.[2] Katz, in one-half the cases with this syndrome, observed the existence of heart disease of either inflammatory (rheumatic, syphilitic, etc.) or degenerative type.

The most common pathologic findings are interstitial edema, vacuolar degeneration of the myocardial fibers, chronic rheumatic myocarditis, and scars near the AV node.

[2] Good evidence in favor of an aberrant bundle has been gathered, including histologic studies (Chap. 10). *Editor.*

heart; *dizziness* and *faintness* may occur if the sinus pauses are prolonged.

Diagnosis. The diagnosis of SA block may be suspected clinically but can best be made by means of the electrocardiogram.

Electrocardiogram. In the electrocardiogram, there is a pause or series of pauses, each one of which is slightly less than double the normal P-P interval, *occasionally, the pause is exactly equal to that of two normal cycles.* Both the atrial and the accompanying ventricular complexes are lost during the pauses (Fig 11-16) The duration of the SA block may vary as follows. (1) the irregularity may be observed for a few cycles, (2) the rate may be suddenly halved, dropping, for example, from 75 to 38 per minute—this slow rate may persist for several minutes or longer, (3) the disturbance may be present for long periods of time and may be the underlying mechanism for long-continued bradycardia

Because SA and AV block are due to somewhat similar factors, it is not surprising that these two irregularities are frequently associated

Treatment. No treatment is required in the absence of symptoms or signs. However, when the sinus rate drops to a low figure with the resultant production of syncopal attacks (more common in the older age group), it is advisable to administer certain drugs to diminish or eliminate vagal tone, e g , Isuprel, 10 mg, sublingually, ephedrine sulfate, ⅜ gr (25 mg) three times a day, or other sympathomimetic drugs or atropine sulfate, or Banthine Drugs which would increase vagal tone, such as Prostigmine or digitalis, should be omitted or used with caution Toxicity due to quinidine, procaine amide, or potassium, which may be an additional causative factor, should be appropriately treated

PROLONGED SINUS PAUSES (CARDIAC STANDSTILL) AND ATRIOVENTRICULAR NODAL ESCAPE

If, for any reason, the SA node fails to initiate the cardiac impulse, the AV node, because it also possesses the property of rhythmicity to a degree only slightly below that of the SA node, soon "escapes" and initiates the heart beat It maintains a slow and regular rhythm until the SA node can again resume its function as the pacemaker. Ordinarily, the AV node is prompt to assume its pacemaker function In certain instances, however, this assumption may be delayed, with the result that there is complete cardiac standstill. This asystolic state may be of sufficient duration to produce dizziness or even syncopal attacks. Such pauses are the result of vagal effects which may occur spontaneously as a result of reflex disturbances or may be produced in susceptible individuals by carotid sinus pressure. These seizures usually respond to atropine or ephedrine If the AV node fails to take over the role of pacemaker, a ventricular center, usually located in the upper portion of the interventricular septum, may assume this role. This phenomenon is called "ventricular escape" If the periods of cardiac standstill are unduly prolonged because of failure of the AV node or an idioventricular center to assume temporarily the role of pacemaker, cardiac arrest or ventricular fibrillation ensues. Such episodes are particularly apt to occur as the result of depression of the conducting tissue by anesthesia, hypoxia, potassium, or full doses of quinidine or procaine amide.

WANDERING PACEMAKER BETWEEN THE SINOATRIAL AND ATRIOVENTRICULAR NODES

Under conditions of increased vagal tone, the rhythmicity of the SA node becomes reduced and that of the AV node remains the same or increases somewhat. Consequently, the function of the pacemaker shifts to the AV node. With a subsequent decrease in vagal tone, the pacemaker returns to the SA node. As seen on the electrocardiogram, this shift is not sudden but occurs over a space of several beats Progressive changes are seen in the P waves during the shift They undergo change in size, shape, and direction simultaneously, with a shortening of the P-R interval until the classic "high nodal" pattern is achieved (inverted P wave with a P-R interval of less than 0.10 sec) With a return of the pacemaker to the SA node, these changes occur in reverse. At times, P waves, transitional in form, are observed They are thought to be due to the simultaneous firing of the SA and AV nodes. Since the shift of pacemaker function is not abrupt, there must be a phase in which each node has partial pacemaker activity, and thus two impulses traverse the atrial muscle in op-

Etiology. SA block is observed as a normal finding in individuals presenting an increased vagal tone. By itself, it is not considered abnormal. It may be produced in a susceptible individual by carotid sinus pressure. It is also observed in infectious states, during acute rheumatic carditis, in the presence of arteriosclerotic processes involving the SA node, and as a result of digitalis. Quinidine, procaine amide, and hyperpotassemia may also produce this condition; however, these drugs tend to depress atrial contraction relatively early without concomitant effects on the ventricles; thus, they produce AV dissociation and ultimately sinus arrest with the maintenance of ventricular beats.

Pathology. No characteristic pathologic findings are observed in SA block. It may occur in patients with disease of the SA node due to rheumatic carditis or degenerative conditions, it may follow occlusion of the right coronary artery, which supplies the SA node in 60 per cent of hearts. Occasionally, an arteriosclerotic process present in the region of the carotid sinus may tend to produce SA block by its increase of vagal tone.

Symptoms. No symptoms are usually observed with SA block. This arrhythmia may, however, produce symptoms under the following circumstances. Occasionally, the period of block may be prolonged to several seconds, resulting in syncopal attacks However, the periods of cardiac standstill are frequently shortened by the temporary assumption of the role of pacemaker by the AV node (*nodal escape*) or by a ventricular focus (*ventricular escape*). Such episodes may result in a sensation of palpitation or forceful beating of the

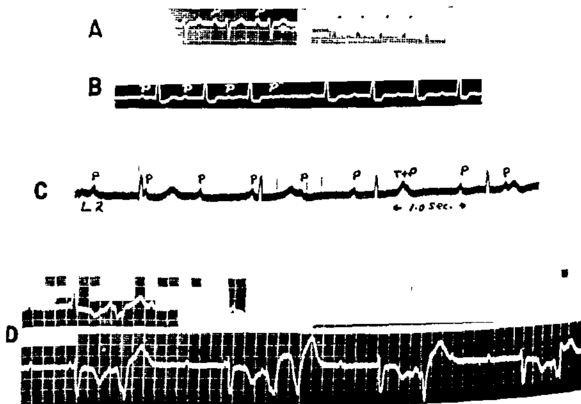

Fig. 11-16. A Partial AV block. Initial strip shows prolongation of the P-R interval, which measures 0.22 sec. Second strip. note the P-R interval prolongation with the tachycardia (ventricular rate, 150 per minute). Note that the P wave of the prolonged P-R interval immediately follows the preceding QRS complex, coming between the QRS complex and the T wave. This P wave controls the following QRS complex. B Partial AV block. Progressive increase in the prolongation of the P-R interval until a dropped ventricular beat is observed at P_X (Wenckebach phenomenon). C. Complete AV block. The atrial rate is 100, the ventricular rate is 37 per minute. Each pacemaker is beating independently of the other. D. Complete AV block with ventricular extrasystoles, some of which appear in groups of two in succession Note the regular atrial rate of 88 per minute and a regular but slow ventricular rate (16 per minute) in most cycles, the two rhythms are entirely independent of each other.

should lead one to suspect the diagnosis (see Chap. 7).

In partial block (2:1), exercise or amyl nitrite may abruptly double the *ventricular rate.* When the *apical rate is regular and ranges from 20 to 40 per minute* and is relatively *unaffected by exercise or atropine,* complete AV block should be suspected. The 1st *heart* sound [illegible] AV

[illegible]

relatively loud; when *they are far* apart, the 1st *sound is faint* (*see also* Chap. 8). The independent movements of *the atria* are usually visible upon a fluorescent screen.

The auscultatory phenomena in AV block should be differentiated from premature systoles, *SA* block, sinus arrhythmia, sinus bradycardia, and AV *nodal rhythm.* A 3:2 AV block *may simulate a* bigeminal rhythm The diagnosis is clearly established by the electrocardiogram.

ELECTROCARDIOGRAM. Partial AV block is recognized easily by the electrocardiogram, *which clearly shows regularly* recurring, normally shaped P waves with prolonged P-R intervals (Fig 11-16) *The* P-R *interval is* prolonged to over 0.21 sec in adults *and over* 0 18 sec in children With a higher grade of partial block, dropped beats may be detected However, prolongation of the P-R interval or nonconducted atrial impulses of other etiologies *must* be excluded. Thus, in atrial premature systoles and *in the atrial* beat *occurring at the* time of the nodal escape, prolonged P-R intervals, nonconducted atrial impulses, or both, may be observed AV dissociation and interference dissociation may also be associated with P-R interval prolongation not due to partial AV block (*see* Chap 11) In all these instances, the atrial *impulse* reaches the AV junctional tissue during its normal relative or absolute refractory phase In AV block, on the other hand, the cause for the disturbance resides in a depression of the AV junctional tissue

Complete Atrioventricular Block. In complete AV block, the atria beat *regularly* at a *rate of* 70 to 80 per minute in response to their pacemaker, the SA node, and the *ventricles* also beat regularly at a rate of 20 to 40 *per minute* in response to their center located in the lower portion of the AV node, in the bundle of His, or *in the upper portion* of the interventricular septum. These *two pacemakers function entirely independently of each other. The atrial* rate is influenced by the vagus and by factors which influence sympathetic tone. With normal sinus rhythm, the ventricular rate is controlled entirely by the events occurring in the atria In complete *AV block,* this situation no longer holds true since the ventricles presumably have no vagal innervation, *therefore, they* usually are not influenced *by changes* in vagal tone. The *ventricular rate,* however, can vary *to some slight degree,* being modified by factors that alter sympathetic tone, such as fever and the injection of epinephrine or other sympathomimetic drugs. If the idioventricular pacemaker is located in the lower portion of the *AV node, terminal* fibers of the vagus may partially control it. In such cases, a *large dose of atropine may slightly* increase *the ventricular rate*

ELECTROCARDIOGRAM. The electrocardiographic diagnosis is easily made (Fig 11-16). The ventricular complexes occur regularly and slowly. While the ventricular rate is usually slow, 30 to 40 per minute, it may be higher *(60 per minute) in complete heart block due* to digitalis; in the cycles immediately following emergence *from Stokes-Adams* seizures, it may be 100 per minute. The atrial complexes usually occur regularly at a normal rate. Occasionally, the atrial rate is quite rapid, 110 to 150 per minute; rarely it is slow, below 40 per *minute. Occasionally, sequences are observed* where two atrial beats are followed by one *ventricular complex,* thus resembling a 2:1 heart block *The Stokes-Adams syndrome* is characterized by syncopal *attacks,* convulsions, or epileptiform seizures, and occurs *when there* is a period of anoxia lasting over 3 to 9 *sec* These episodes are the *chief hazard* and usual cause of death in patients with complete AV *heart block. The following* are the underlying *mechanisms recorded* electrocardiographically during the *seizures* (Fig. 11-17): (1) a prefibrillatory type of *ventricular tachycardia* (ventricular flutter), (2) ventricular fibrillation, (3) standstill of the whole heart, *(4) ventricular* standstill with maintenance of atrial beating *These mechanisms may* occur either singly or in *various* combinations.

TREATMENT. *Complete Atrioventricular Heart Block* No specific therapy *is* indicated

posite directions, giving rise to the isoelectric or transitional P wave. Such beats are said to be *fusion beats.*

ATRIOVENTRICULAR BLOCK

Partial Atrioventricular Block. Atrioventricular (AV) block may be divided into two types: partial, or incomplete, and complete. AV block may be *temporary, intermittent,* or *permanent,* and one type may develop into the other. The first stage of AV heart block is said to occur when the AV conduction time (P-R interval) exceeds 0.20 sec As the degree of block increases, the AV conduction time becomes longer and longer until dropped beats occur, i e., the ventricles fail to respond to some atrial beats. In a still higher grade of block, there may be observed 2:1, 3:1, or an even higher degree of partial AV block As the block further increases, a stage is reached in which the ventricles fail to respond to *any* atrial impulse, with the result that ventricles and atria beat entirely independently of each other When this stage is reached, the degree of AV block is said to be *complete*

Sudden death may occur during the transition from partial to complete block because of ventricular standstill or ventricular fibrillation.

Clinical heart block has been observed as the result of the following. (1) infections, (2) certain drugs, especially digitalis and, to a lesser degree, quinidine and Pronestyl; (3) congenital cardiac anomalies, (4) vagal stimulation; (5) degenerative conditions; and (6) hypoxia. A discussion of these conditions follows

PATHOLOGY. Coronary artery disease, acute or chronic, is the most common cause of AV block in the older age group. The right coronary artery supplies the AV node in 92 per cent of hearts, the left coronary in 8 per cent Gummata occurring in the AV node or bundle of His are rare (see also Chap. 5)

SYMPTOMS AND SIGNS In partial AV block, no symptoms due to the block itself may be observed, even with a slow ventricular rate The symptoms are those of the underlying disease. Some patients with complete AV block present no symptoms, usually, however, they complain of fatigue on exertion, occasional precordial pain, and consciousness of a vigorous, slow, forceful heart action. These patients usually cannot engage in strenuous physical exertion but generally do fairly well on a reduced physical regimen.

As a result of the slow rate, alterations in the cardiovascular dynamics appear. The cardiac output per beat is increased, but the cardiac output per minute, as compared to the normal, may be decreased in some patients. In complete AV block, because of the fixed cardiac rate, the mechanism for increasing cardiac output in response to exertion and excitement is seriously impaired. Exertion may lead to the production of an extrasystolic arrhythmia and, if continued, may precipitate a Stokes-Adams attack. The systolic blood pressure is elevated, rising to about 170 to 200 mm; the diastolic pressure is usually low, 80 to 100 mm. It is distinguished from true hypertension by the relatively low diastolic pressure resulting from the longer emptying time available to the large arteries between heart beats. The systolic pressure rise is evidence of the enhanced vigor of the slow beats resulting from the greater filling time allowed the heart. The heart, particularly the left ventricle, is enlarged

The important symptoms to be considered in the higher grades of partial and complete AV heart block are the development of *giddiness, fainting,* and *temporary loss of consciousness, with or without convulsive seizures (Stokes-Adams syndrome).* These manifestations of cerebral hypoxia occur during the transition from partial to complete AV heart block, as well as during the course of complete cessation of cerebral flow for 3 to 9 sec or longer.

DIAGNOSIS. The possibility of AV block should be suspected in the presence of any of the conditions mentioned above, especially rheumatic fever, coronary diseases, digitalis, toxic factors, etc. Suggestive evidence consists in a *diminished intensity of the 1st heart sound,* which may be marked. In the presence of dropped beats, the auscultatory phenomena closely resemble and should be differentiated from extrasystoles with a compensatory pause. When there is a delay in AV conduction (prolonged P-R interval) with a regular rhythm ranging from 50 to 80 per minute, the diagnosis is practically impossible by auscultation alone. With rates below 50 or 40 per minute, the possibility of partial or complete heart block should be considered. The presence of a jugular pulse more rapid than that of the apex

1 to 2 hr, depending on desired results, or may be given as a 1:1,000 solution in oil (1.0 ml intramuscularly).

3. *Isuprel* may be given sublingually in doses of 10 to 20 mg every 2 hr or as required, subcutaneously 0.2 mg every 6 hr or as indicated, or intravenously as a continuous infusion of 1 mg Isuprel dissolved in 200 ml of 5 per cent glucose in distilled water, or 4 μg per ml, at a rate of 9 to 20 drops per minute.

4. Molar sodium lactate is effective when given promptly, preferably within 1 to 2 min after the onset of the attack. Initially, it should be given intravenously by syringe in doses of 20 to 40 ml in 1 to 2 min during the attack; then, the solution should be administered as an intravenous infusion at the rate of 60 to 150 drops per minute, the exact rate and amount depending on the effects observed. As the ventricular rate increases, the infusion should be slowed; when it becomes apparent that the pacemaker is spontaneously maintaining a satisfactory rate and the episodes of cardiac arrest have been eliminated, the infusion should be stopped.

5. An *artificial pacemaker* will restore cardiac beating during cardiac arrest. Its use may be lifesaving (see Chap. 12).

6. Because these seizures are so often repeated, thoracotomy accompanied by cardiac massage should be used only when all other methods fail.

7. *Barium chloride* increases the rhythmicity of the cardiac pacemaker but is not frequently used because of its toxic effects.

8. Quinidine and procaine amide have been used in the past when the Stokes-Adams seizures were associated with ventricular extrasystoles, ventricular tachycardia, or ventricular flutter. The administration of these drugs is considered to be contraindicated because they depress cardiac pacemakers.

9. Digitalis in the presence of congestive failure should be used with caution because of its effect in increasing cardiac irritability. AV block, if complete, is not a contraindication to the use of digitalis. Incomplete AV block, on the other hand, might be transformed into complete block by digitalis.

10. Defibrillation may be accomplished by application of the *defibrillator* (see Chap. 12) to the closed chest or after thoracotomy to the exposed heart.

for the *asymptomatic* type of AV block; these patients do fairly well with a slow rate, which may range from 30 to 40 per minute. In the *symptomatic* type of AV block, in which the patient experiences frequent fainting episodes, administration of one or more of the following drugs is indicated: (1) sympathomimetic drugs (ephedrine, Isuprel), (2) oral molar sodium lactate.

Stokes-Adams Seizures. Prophylaxis consists of avoiding those factors which tend to precipitate attacks; e g., strenuous exertion and emotional upsets. Between attacks, measures as described for AV block may be used. The active measures during an attack consist of the following:

1. Direct vigorous thumping on the precordium.

2. *Epinephrine* by intracardiac injection (0 25 to 1 ml of a 1:1,000 solution). This may also be given by slow-drip intravenously, but not more than 0.25 mg should be given by this route, and the drug must be administered at a very slow rate. To prevent repeated attacks, epinephrine may be given in doses of 0.2 to 0.3 ml subcutaneously every

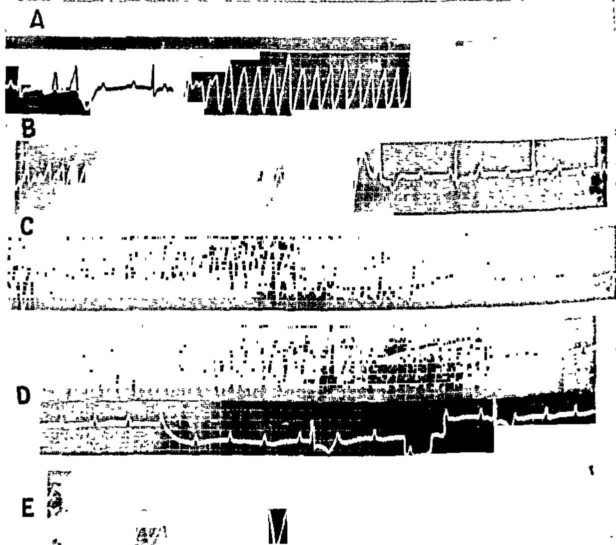

Fig. 11-17. Cardiac mechanisms during a Stokes-Adams attack. Strips A, B, C, D, and E are taken from the same patient, who had a complete AV block A. Paroxysm of *ventricular flutter* with a ventricular rate which averages about 200 per minute Note the markedly aberrant type of ventricular complexes. The end of the strip shows the resumption of the *complete AV heart block* B. Ventricular flutter with a rate of about 200 per minute, terminating in *ventricular standstill*. The atrial rate is maintained at 100 per minute. C. Emergence from an attack of *ventricular standstill*, with the appearance of occasional idioventricular beats. D, and E. *Ventricular fibrillation*. Note the markedly aberrant type of ventricular response. The patient recovered from this paroxysm but succumbed during a subsequent attack.

arteries nearer the heart but not in those more distant When failure is severe, a high pulse wave may be followed by gradually smaller ones (*Galenus's pulse*).

As long as the conditions of the myocardium are good, the *stroke volume* is directly proportional to the length of the preceding diastole and inversely proportional to the stroke volume of the preceding cycle. (This, however, is approximate and not exact.) If there is cardiac failure, no rule can be established The *speed* of the small pulse waves is always greater than that of the large waves

Electrokymogram. This tracing has been studied by Lewis and Terry, Boone et al., and Engstroem et al The atrial tracing shows the absence of atrial waves The waves of the ventricular and arterial tracings (both the aortic and the pulmonic) have a variable amplitude, which is roughly proportional to the length of the previous diastole

PREMATURE BEATS

Jugular Tracing *Atrial premature beats* have A, C, and V waves which are similar to those of a normal tracing *Nodal* and *ventricular premature beats*, on the other hand, frequently have a high A wave, because of simultaneous atrial and ventricular contraction which is accompanied by a venous regurgitant wave

A *left ventricular premature beat* may show a delay of V over the 2d aortic sound (early contraction of the left ventricle, later contraction of the right, with late opening of the tricuspid valve).

Arterial Tracing, Hemodynamics. The pulse wave of the premature beat may be as high as a normal wave and occasionally higher *It is usually smaller and may be absent* on account of small ejection or even lack of ejection. Records taken over different arteries *show that* the pulse wave of the *premature* beat may be present in the arteries near the heart (carotid) and absent in those distant (tibial arteries) A drop in pressure occurs during the compensatory pause The following wave is higher than normal, and is followed by a smaller wave; this may start a *pulsus alternans*

The pulse of the premature contraction has a low systolic and a high diastolic pressure, while the following pulse is much larger, having a high systolic and a low diastolic pressure.

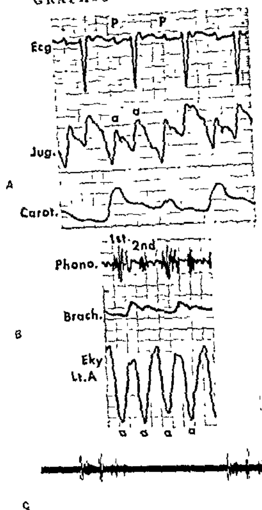

Fig. 11-18. Tracings revealing a greater number of atrial waves than ventricular waves. A. Multiple waves of atrial origin in the jugular tracing of a patient with atrial flutter B Multiple waves in the left atrial border electrokymogram of a patient with atrial flutter. C Multiple waves in the right atrial border electrokymogram in a patient with complete AV block Above, phonocardiogram; below, EKy.

From *two to three* pulse waves are necessary *for reaching* again a normal and stable level of blood *pressure*. On the other hand, the first normal contraction following *an interpolated premature beat* frequently yields a smaller *pulse* wave in the peripheral arteries (a short *diastole* precedes such an extrasystole).

The pulse wave of a *right* ventricular premature beat *may* be delayed over the beginning of the corresponding *1st* apical sound

Graphic tracings in arrhythmias and atrioventricular block

ALDO A. LUISADA

SUPRAVENTRICULAR TACHYCARDIA

Jugular Tracing. There is only one high wave, owing to fusion of the various waves If the atrial and ventricular contractions occur exactly at the same time, this venous wave becomes high, because if the right atrium cannot push the blood forward against the closed tricuspid valve, it will push it backwards, into the large veins

Arterial Pulse. The pulse becomes small during the attack. The dicrotic wave, however, may be relatively higher, and its fusion with the following pulse wave may simulate an anacrotic pulse The speed of the pulse wave is often reduced

VENTRICULAR TACHYCARDIA

Jugular Tracing. High atrial waves are recorded, at a rate which is slower than that of the arterial pulse (unless there is atrial fibrillation). The waves may be slightly irregular

Arterial Tracings. The pulse waves are small and may show a variable height, then, a higher wave is caused by the casual precedence of an atrial contraction over a ventricular. There may be *pulsus alternans.*

ATRIAL FLUTTER

Low-frequency Tracing of the Precordium. Atrial waves may be recorded in the intervals between the ventricular waves of this tracing.

Jugular Tracing. Regular atrial waves were recorded by several workers. More recently, Contro has recorded high atrial waves in five cases of flutter by means of a linear microphone and an amplifier. These waves give evidence of the coordinated contractions of the atria.

Electrokymogram. If the slit of the pickup is placed across the border of either atrium, good evidence of atrial contractions can be secured (Fig. 11-18A, B). The atrial waves are usually of large amplitude, and their detection is important in cases where the electrocardiographic tracing had led to admission of "impure fibrillation."

ATRIAL FIBRILLATION

Jugular Tracing. The C and V waves follow each other with complete irregularity. There are no A waves, because of the fibrillation

Low-frequency Tracing of the Precordium. The waves caused by ventricular contraction are of various height and configuration. When diastole is short, the subsequent isometric tension period becomes longer. The height of the waves varies somewhat but is not exactly proportional to the length of the preceding diastole.

Arterial Tracings, Hemodynamics. The pulse waves are typically irregular, having various heights, lengths, and configurations Patients in congestive failure often have a *pulse deficit* because some of the ventricular contractions have such a small ejection that they are not followed by a pulse wave. However, when ejection is small, waves may be present in the

8

Phonocardiography in arrhythmias and blocks

ALDO CALO

SUPRAVENTRICULAR TACHYCARDIA

The findings during the attack should be considered separately from those obtained after reestablishment of sinus rhythm. The latter may be considered as the result of a posttachycardial phonocardiographic syndrome

The Attack. Increased loudness of the 1st sound is frequent. Even though loudness may progressively increase during the first few beats of the attack, once the maximum loudness has been reached, the 1st sounds continue with the same magnitude, small variations in amplitude may be due to respiratory variations The increased loudness of the 1st sound may be caused either by summation of the 1st with the 4th (atrial) sound, or by changes in the mechanism of closure of the AV valves

In *low nodal tachycardia with retrograde conduction*, the atrial sound may show up in the tracing soon after the 1st sound, causing *splitting of the 1st sound* (Fig. 11-19A) Actually, it is not a *real splitting* but the addition of a *new sound* (atrial) in early systole *Alternans* is exceptional If present in the above cases, alternans affects *only* the ventricular *component*, *i e*, the 1st sound, while the *atrial* sound is unaffected. The *2d sound may be* accentuated, split (either occasionally or continuously), or small, to the *point* of disappearance Both *systole and diastole* are markedly *shortened*, the latter more than the former As diastole becomes progressively *shorter* and the atrial contraction is closer to the rapid filling of the preceding cycle, a *summation type of triple rhythm* (*summation* gallop) occurs. Several *murmurs* may appear during attacks of tachycardia of long duration. They have been explained as the result *of increased speed of* flow, changes *of the* normal sequence of atrial and ventricular contractions, or relative insufficiency of the mitral valve The latter *might* be due to ventricular dilatation as a result of strain On the contrary, preexisting murmurs caused by valvular lesions *or shunts may disappear during an* attack.

Posttachycardial Syndrome. The phonocardiographic signs of this syndrome *may consist of changes of the sound* and murmurs present before the attack; disappearance of signs brought about by the attack itself; return of signs obscured by *the attack*, and, finally, appearance of new phonocardiographic data. After sinus rhythm is reestablished, the following may be found: 1st *and* 2d sounds—true or false splitting, alternans may either decrease or disappear. Systole and diastole regain their normal values A summation *type* of triple rhythm, originated by the attack, may disappear. *On the* other hand, a new triple rhythm may appear after the attack because of myocardial insufficiency. The same may be said for *murmurs which* may disappear, *reappear, or start* after the attack. These murmurs are usually of mitral origin and *are functional.*

ATRIAL FLUTTER

In most cases, the *atrial sounds*, which on *occasion may* become abnormally large and even clinically audible, may have no time re-

(earlier contraction of the right ventricle, subsequent contraction of the left, responsible for the pulse).

The *stroke volume* varies greatly, being inversely proportional to the length of the preceding diastole. Therefore, the earlier the contraction, the smaller the stroke volume. The compensatory pause is followed by a contraction which has a proportionally larger stroke volume. This, however, is not true if the myocardium is weak.

The speed of the pulse wave is directly proportional to the level of diastolic pressure; therefore, the weak pulse of the premature contraction has a greater velocity than the others.

Blood Pressure Tracings. Different levels of blood pressure can be obtained if the premature beats occur periodically. (1) those corresponding to the systolic and diastolic pressure of the normal pulse waves, (2) those corresponding to the pulse waves of the premature beats (low systolic, high diastolic); and (3) those corresponding to the pulse waves immediately subsequent to the premature beats (high systolic, low diastolic).

Low-frequency Tracing of the Precordium. The premature contraction may give waves of normal configuration The isometric tension period is often prolonged. This may cause bizarre or large waves.

Electrokymogram. Premature contractions are easily studied by means of border tracings of the left ventricle, the pulmonary artery, or the aortic arch If simultaneous tracings of the left ventricle and one of the arteries (aorta or pulmonary artery) are taken, conclusions may be drawn about the site of origin of a ventricular premature beat. The aspect of the tracing depends upon the time of the cardiac cycle at which the premature contraction occurs and the phase of the ventricular filling

If the contraction starts early in diastole, its amplitude is small, isometric contraction is prolonged, and the curve assumes a more peaked aspect. The isometric tension period may last more than 0.06 sec on account of both the high level of arterial pressure and the small amount of ventricular blood If the contraction takes place immediately after the T wave, no ejection may occur During the compensatory pause, an abnormally large filling of the ventricles takes place. This, plus the lower level of arterial pressure, causes a shortening of the isometric tension period of the following contraction.

ATRIOVENTRICULAR BLOCK

Jugular Tracing. The A waves are normal in shape and follow each other, usually, at a normal rate; the C and V waves occur at regular, but much longer, intervals. Therefore, more than one A wave is found between a V wave and the next C wave. Occasional coincidence of an A wave with a C or V wave may occur, with a resulting higher wave.

Arterial Tracing. A high and slow pulse is recorded. An anacrotic depression is frequently present in the ascending branch of the pulse curve. Multiple undulations follow the dicrotic wave.

In *occasional block*, the tracings reveal the occasional absence of a pulse wave (*intermittence*). In *periodic block*, the series of pulse waves shows a periodic increase in the pause separating two pulses, then a longer pause with a deeper pressure drop. *Interference dissociation* may cause a bigeminal rhythm, the second wave being paradoxically *higher* than the first (Fischer).

Low-frequency Tracing of the Precordium. High atrial waves are present between the waves caused by the ventricular contractions

Electrokymography. The electrokymogram of AV block has been studied by the author, Engstroem et al., and Pannier et al

ATRIAL TRACINGS If atrial contraction falls during ventricular systole, the atria decrease in volume as in normal subjects; apparently the blood is pushed backwards into the veins. If the atrial contraction falls during ventricular diastole, the pattern consists of an oblique, descending line during atrial contraction, and a less steep rise subsequent to it. The depth of the contraction varies, it is usually larger when the atrial contraction falls during a ventricular contraction because of additional ventricular pull (Fig. 11-18C).

LEFT VENTRICULAR TRACING. The tracing of the left ventricle may not show any effect of the atrial contractions. If it does, the latter are revealed by small positive waves.

lationship with the main heart sounds. In other cases, changes of cardiac sounds, murmurs, and intervals may be produced by a profound alteration in the hemodynamics caused by the disturbance of rhythm (Fig. 11-19B). The atrial sounds recorded from the esophagus start 0 04 sec after the P waves, most likely they are produced within the atria The atrial sounds recorded over the precordium are far more delayed because they start from 0 14 to 0 24 sec after the P waves and 0 10 sec after the A waves of the jugular tracing Thus indicates that the precordial atrial sounds are originating either in the ventricular walls or in the AV valves. In general, each atrial sound consists of a single group of 1 to 4 low-pitched vibrations, lasting from 0 03 to 0 08 sec. Exceptionally they last 0 16 sec and present two separate components, one with a single high vibration, and the other with several lower vibrations (see Atrioventricular Block, further on in this chapter, for explanation) The amplitude of atrial vibrations is usually small, but in certain cases they may be one-half of either heart sound Sounds produced during systole are often higher than those originated in diastole In irregular flutter, the amplitude of these sounds is variable and some of them may be absent in spite of ECG evidence of atrial contractions The modifications of cardiac sounds, murmurs, and intervals produced by *regular flutter* are constant, while variable and inconstant findings are found in *irregular flutter*, where marked changes of dynamics occur

The changes of the 1st sound are closely related to the duration of the P-R interval or P-1st sound interval, which are equivalent For values between 0 08 and 0 12 sec, the 1st sound is increased in loudness (an occasional increase is typical of irregular flutter) For higher or lower values, the 1st sound either may be decreased or may present a systolic or presystolic addition of an atrial sound (*pseudo splitting*) The *1st sound* may be delayed over the beginning of the QRS complex, may be of small amplitude, and may be alternating The *2d sound* may be increased, decreased, or split In irregular flutter an occasional accentuation may be due to addition of an *atrial sound* to the 2d sound At times, the 2d sound may disappear because of weak ventricular systole, as in some types of extrasystoles or cases of atrial fibrillation. A *summation type* of triple rhythm can take place whenever an atrial contraction coincides with the phase of rapid ventricular filling. In regular flutter, this may happen after every ventricular systole; in irregular flutter, it may happen occasionally.

It is a common notion that the *presystolic murmur* of mitral stenosis disappears whenever the left atrial contraction fails to occur. The fluttering left atrium may display such a powerful systole as to accelerate the flow across the mitral valve. This results in *a loud murmur for every atrial contraction* which takes place in diastole (in systole, it is obvious that the atrium cannot open the mitral valve). The *systolic murmur* of mitral insufficiency may disappear or change in character during atrial flutter, and it may reappear or increase after reestablishment of the sinus rhythm.

ATRIAL FIBRILLATION

Atrial fibrillation is characterized by a complete arrhythmia of cardiac sounds and murmurs with irregular variations for every cycle. An exception is represented by rare cases with idioventricular rhythm

Cases without Valvular Lesions. The 1st sound is usually *delayed* over the R wave but this delay is *small*. Its amplitude and duration are variable, so that the 1st sound may become quite small or very large Apparent splitting is frequent; this may be due to a separation of the valvular components or, in the case of a very short diastole, to the occurrence of a ventricular type of triple rhythm (gallop) immediately followed by the 1st sound (Fig 11-19C) *The 2d sound usually presents* continuous changes of amplitude and duration which are independent from those of the 1st sound There also may be an occasional splitting due to asynchronism of the semilunar valves

In some cases, the apical phonocardiogram may show *a short systolic murmur*, which, in the absence of any valvular lesion, is thought to be due to functional mitral insufficiency or to the formation of eddies Even though no atrial or summation type of triple rhythm may occur on account of the lack of atrial contractions, various types of triple rhythm may occur. These are due to the addition of a ventricular sound which may fall in early diastole, mid-diastole, or just prior to the following 1st

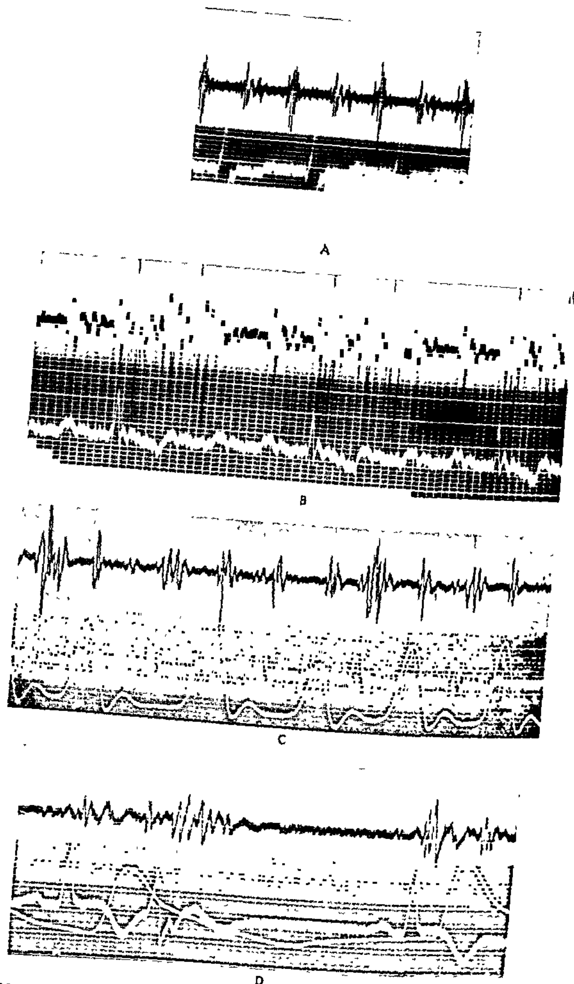

Fig. 11-19. A. Supraventricular tachycardia. Phonocardiogram (stethoscopic) 2R2. B. Atrial flutter. Phonocardiogram (stethoscopic) 2R2. C. Atrial fibrillation. Phonocardiogram (stethoscopic) 5L7-O S. D. Ventricular extrasystole. Phonocardiogram (stethoscopic) 4R2 Od.

and murmurs may disappear if present, or, on the contrary, may appear during the attack.

2 *Posttachycardial syndrome.* Decreased loudness of the cardiac sounds, murmurs due to relative valvular insufficiency, and triple rhythm are frequent. Following ventricular tachycardia, one can see a marked decrease in amplitude of the 1st sound, a systolic murmur in decrescendo, and a triple rhythm (summation type). The last two had disappeared during the attack but were previously present.

NODAL RHYTHM

The changed time relationships between atrial and ventricular systoles cause marked changes of the phonocardiogram. If present, an atrial *4th sound* disappears. The vibrations of the 1st sound, owing to closure of the AV valves, have an amplitude which varies in proportion to the P-R interval. This is because of different tension of these valves at the beginning of systole. In nodal rhythm, the 1st sounds have constant loudness, while in cases of wandering pacemaker, there are continuous changes. A short systolic sound due to atrial contraction may appear.

SINOATRIAL BLOCK

There are only two published phonocardiograms in cases with bigeminal SA block. The cardiac sounds either remain unchanged, or they alternate in amplitude, number of vibrations, and duration (Fig. 11-21A).

ATRIOVENTRICULAR BLOCK

Complete Atrioventricular Block without Valvular Lesions. *Atrial sounds* are present both in systole and diastole (Fig. 11-21B). In esophageal phonocardiograms and, occasionally, in precordial tracings, they present *three groups of low-pitched vibrations:* the first is caused by the atrial contraction, the second seems to be due to the resulting ventricular distention or a vibration of the AV valves, the third, to an elastic recoil of the ventricular walls. In precordial tracings, where the three groups are recorded, they occur 0.04, 0.12, and 0.27 sec after the respective P wave, and the duration of the atrial sound complex is from 0.34 to 0.36 sec. However, the first group of vibrations is seldom recorded. Then the atrial sound complex starts 0.06 to 0.12 sec after the P wave and lasts from 0.15 to 0.22 sec. The atrial sounds during systole consist of one or two groups of vibrations, and they can be larger than the diastolic. Their mechanism of production is still discussed. Some authors feel that these sounds are directly caused by atrial contraction which causes a vibration of the closed AV valves. *Atrial murmurs* can be seen in diastole in older patients 0.14 to 0.23 sec after the beginning of the P wave. These murmurs, occurring *after* atrial contraction, can be explained by sclerosis of the AV valves, which at first hinders their upward movement, causing a moderate regurgitation, and then delays their opening, thus slowing the normal

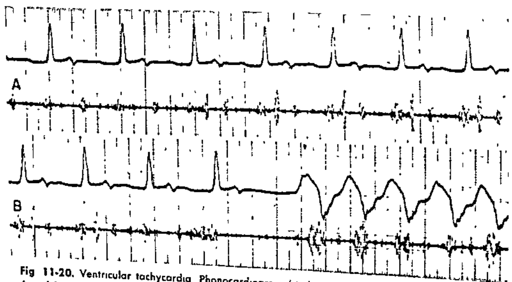

Fig 11-20. Ventricular tachycardia. Phonocardiogram (stethoscopic) 3M. (0.02 in. and 0.10 in.). A and B are consecutive sections of the same tracing.

sound, on account of the variable duration of diastole.

Cases with Mitral Lesions. Frequently the sclerosis of the mitral cusps increases the loudness of the 1st sound and causes its splitting. The Q-1st sound interval, which is particularly prolonged in mitral stenosis, becomes even longer if there is atrial fibrillation. This interval is inversely proportional to the duration of the preceding cardiac cycle: shorter diastole = longer interval (Luisada, Cossio). The *opening snap* of the mitral valve has duration and intensity which vary for every cycle (Rappaport and Sprague; Wells). This snap is more distant from the 2d sound when left atrial pressure is lower; therefore, it is more distant after a long diastole. *Murmurs* of mitral origin are known to disappear when atrial fibrillation starts. This is particularly true for the presystolic murmur, while the systolic and the mid-diastolic murmurs may disappear for a time and reappear later. On the other hand, the mid-diastolic murmurs of mitral stenosis may be louder than in cases with sinus rhythm. This may be explained by the fact that left atrial pressure is higher. A *ventricular type* of triple rhythm is frequent in mitral insufficiency, occasionally present in moderate mitral stenosis, and absent in severe mitral stenosis. It may simulate an opening snap

EXTRASYSTOLES

Extrasystoles (Fig. 11-19D) are characterized by the premature appearance, and possibly by the occasional absence, of cardiac sounds and murmurs Other possible signs are due to the extrasystole itself. Others may affect the preceding cycle (preextrasystolic signs) and some of the following beats

The 1st sound is usually accentuated and delayed, the Q-1st sound interval being from 0 08 to 0 10 sec and even 0.12 sec The main vibrations may be from two to four times higher than those of the normal contractions Sometimes the 1st sound is decreased and may be completely absent, it may be either shortened or prolonged, it may be split, but this is seen only in ventricular extrasystoles, on account of marked asynchronism of closure of the mitral and tricuspid valves.

Ventricular systole is usually short The *2d sound is usually small* and may become so faint as to disappear. This is more frequent in cases of early extrasystoles, especially if they are interpolated. Absence of both sounds is extremely rare; in such cases, *the extrasystole is clinically mute.* Because of asynchronism of the closure of the semilunar valves, splitting of the 2d sound may occur in ventricular extrasystoles. On the other hand, previous splitting of the 2d sound may disappear during the extrasystole.

Triple Rhythms. The atrial type disappears in ventricular extrasystoles because of the absence of atrial contractions. On the other hand, following an extrasystole, a ventricular type of triple rhythm may occur, or it may disappear if it was regularly present in the normal cycles. A summation type of triple rhythm may be seen in atrial or sinus premature contractions It is due to coincidence of the rapid filling of the preceding beat with the following atrial contraction. Extrasystoles may either increase or decrease the loudness of *murmurs* The latter may even disappear during an extrasystole because of inadequate filling of the ventricles

The extrasystoles may modify some of the graphic characteristics of the preceding cardiac cycle For instance, when they occur very early, the 1st sound may coincide with a 3d sound, and even with the 2d sound of the previous cycle This may cause increased loudness of that 2d sound, a summation type of triple rhythm, or an accentuation of the early-diastolic murmur of mitral stenosis. On the other hand, this murmur may disappear if several premature contractions occur in a row.

The 1st sound is frequently increased in the beat immediately following the extrasystole and, at times, in the second or third subsequent beat. Occasionally, *alternans* develops.

VENTRICULAR TACHYCARDIA

The phonocardiographic signs of the ventricular tachycardias are similar to those of the supraventricular forms.

1. *The attack.* During the attack, ventricles and atria beat independently and, now and then, contract at the same time. The 1st sound presents characteristic changes consisting of occasional sudden increase of loudness (Fig 11-20). The 1st sound may be prolonged or split, either constantly or intermittently, and is usually delayed. The 2d sound occurs early (short systole). Diastole is even shorter. As in supraventricular tachycardia, triple rhythms

and murmurs may disappear if present, or, on the contrary, may appear during the attack.

2 *Posttachycardial syndrome.* Decreased loudness of the cardiac sounds, murmurs due to relative valvular insufficiency, and triple rhythm are frequent Following ventricular tachycardia, one can see a marked decrease in amplitude of the 1st sound, a systolic murmur in decrescendo, and a triple rhythm (summation type). The last two had disappeared during the attack but were previously present

NODAL RHYTHM

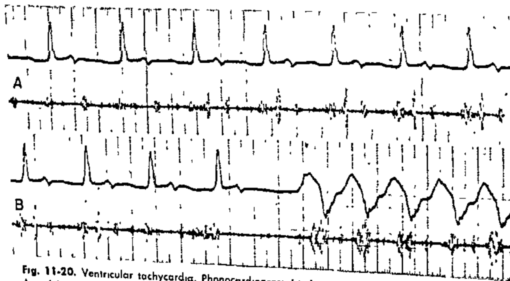
The changed time relationships between atrial and ventricular systoles cause marked changes of the phonocardiogram If present, an atrial *4th sound* disappears. The vibrations of the 1st sound, owing to closure of the AV valves, have an amplitude which varies in proportion to the P-R interval This is because of different tension of these valves at the beginning of systole In nodal rhythm, the 1st sounds have constant loudness, while in cases of wandering pacemaker, there are continuous changes A short systolic sound due to atrial contraction may appear

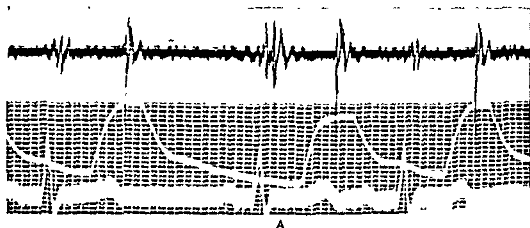
SINOATRIAL BLOCK

There are only two published phonocardiograms in cases with bigeminal SA block. The cardiac sounds either remain unchanged, or they alternate in amplitude, number of vibrations, and duration (Fig 11-21A)

ATRIOVENTRICULAR BLOCK

Complete Atrioventricular Block without Valvular Lesions. *Atrial sounds* are present both *in systole and diastole* (Fig. 11-21B). In esophageal phonocardiograms and, occasionally, in precordial tracings, they present *three groups of low-pitched vibrations:* the first is caused by the atrial contraction, the second seems to be due to the resulting ventricular distention or a vibration of the AV valves, the third, to an elastic recoil of the ventricular walls In precordial tracings, where the three groups are recorded, they occur 0 04, 0.12, and 0 27 sec after the respective P wave, and the duration of the atrial sound complex is from 0 34 to 0 36 sec. However, the first group of vibrations is seldom recorded Then the atrial sound complex starts 0 06 to 0.12 sec after the P wave and lasts from 0.15 to 0 22 sec The atrial sounds during systole consist of one or two groups of vibrations, and they can be larger than the diastolic. Their mechanism of production is still discussed Some authors feel that these sounds are directly caused by atrial contraction which causes a vibration of the closed AV valves *Atrial murmurs* can be seen in diastole in older patients 0.14 to 0.23 sec after the beginning of the P wave. These murmurs, occurring *after* atrial contraction, can be explained by sclerosis of the AV valves, which at first hinders their upward movement, causing a moderate regurgitation, and then delays their opening, thus slowing the normal





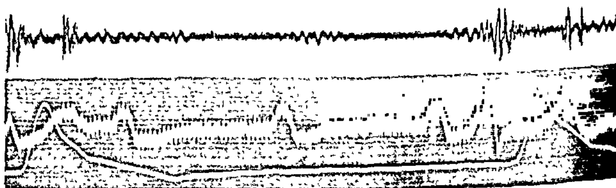


Fig. 11-20. Ventricular tachycardia. Phonocardiogram (stethoscopic) 3M. (0 02 in and 0 10 in). A and B are consecutive sections of the same tracing.

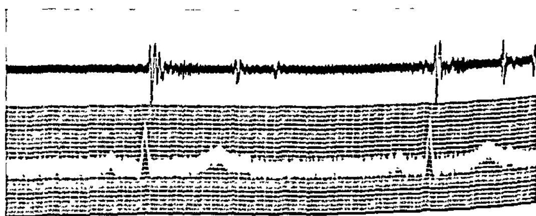
ventricular filling. In other words, slight insufficiency and stenosis would take place in turn, both of them functional and of short duration.



FIRST SOUND. *Splitting* of the 1st sound has been described. It is due to two separate groups of ventricular vibrations. Splitting may be simulated by presystolic or systolic occurrence of an atrial sound. *Changes in amplitude of the 1st sound* are also typical of complete AV block. In long tracings, one can see marked changes in amplitude from one beat to the next. The 1st sound may disappear almost completely, or it may increase in amplitude up to five or six times (*cannon sound*). The frequency, duration, and number of vibrations of the 1st sound usually follow the changes in amplitude. Thus, an increased 1st sound has a higher pitch and more vibrations. A definite relationship has been found between the amplitude of the 1st sound and the duration of

A

B

C

Fig. 11-21. A. Sinus bigeminy. B Complete AV block C. Incomplete AV block with Wenckebach periods. All phonocardiograms (stethoscopic) 5L6

the P-R *interval* For P-R intervals from 0 50 to 0 32 *sec*, the amplitude of the 1st sound is somewhat *increased*, from 0 32 to 0.23 sec, the amplitude is *decreased*; from 0 25 to *0.12* sec, it is moderately increased, from 0 14 to 0 04 sec, it is again *markedly increased* (cannon sound). When the P wave follows *the R wave* and *there is an* R-P *interval of from* 0 04 *to* 0 28 *sec*, the sound *is just slightly increased*

A *dissociated cannon sound* and a *double cannon sound* were described in cases of complete AV block with bundle branch block. The former is due to accentuation *of one of* the two components of a split 1st sound, the latter to accentuation of both components *The* variable amplitude of the 1st *sound has* been explained by the different position of the AV valves at the beginning of the systole and by different tension of their fibrous rings.

A systolic murmur, probably due to relative mitral insufficiency, is frequent. The formation of eddies in an overloaded and distended ventricle could also be considered as a possible cause.

The 2d sound shows changes *in time* and amplitude, and it may *be split*. The sound *is* delayed *in* regard *to the* 1st sound *because of* prolongation *of mechanical systole*, *but may* precede the end of the T wave on *account of* even more prolonged electrical systole. An occasional increase of the 2d sound occurs when the P wave coincides with the end of the T wave. *False splitting* occurs if an atrial sound falls just before the 2d sound, *true splitting* when two valvular components are separate. The former shows the low-grade *vibrations* of the atrial sound, the second has two groups of similar vibrations.

Triple rhythms have the usual graphic characteristics. The additional sound occurs periodically. It may occur intermittently every time that a P wave follows the T wave, i.e., any time that the atrial contraction coincides with rapid ventricular filling.

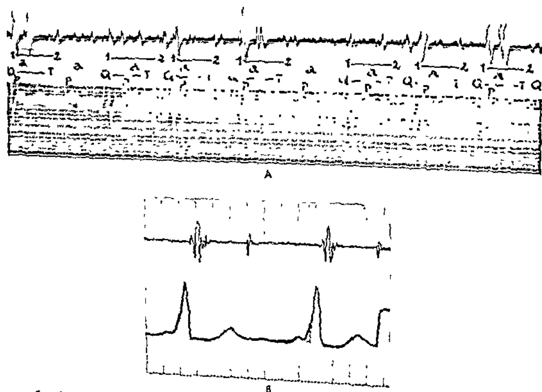


Fig 11-22. A. Incomplete AV block with Wenckebach periods. Phonocardiogram (stethoscopic) 516. B Wolff-Parkinson-White syndrome Phonocardiogram 0–25 cps 517.

Atrioventricular Block with Mitral Lesions. The valvular lesion frequently causes the 1st sound to be less decreased than when the mitral valve is normal. The systolic murmur of mitral insufficiency may decrease or disappear if there is a short P-R interval; this is because atrial contraction somewhat resists the regurgitant jet (only for a short time) and gives a greater tension to the mitral ring. Every atrial contraction may be followed by a *murmur,* during the long diastole, three or four murmurs may be seen with regular intervals and progressively decreasing amplitude. This is because the increased diastolic filling of the ventricles gradually hinders further filling due to atrial propulsion.

Incomplete Atrioventricular Blocks. In a 2:1 block, one may see *two atrial sounds,* one in protodiastole and one in presystole (Fig. 11-21C) The former may coincide with and accentuate the 2d sound, it may fall during rapid filling, thus causing a summation type of triple rhythm, or it may give a delayed diastolic sound. In cases without valvular lesions, every P wave may be followed by an atrial murmur, as in complete AV block, in cases with mitral stenosis, the P wave may be followed by a loud diastolic murmur. In both cases, a short systolic murmur is also usually present. In *Wenckebach periods,* the diastolic atrial sounds parallel the cyclic variations of the P-R interval. This holds true both for the presystolic murmur of mitral stenosis and for the atrial sounds and murmurs in cases without valvular lesions (Fig 11-22A). The magnitude of the 1st sound varies according to the duration of the P-R interval; it may become progressively decreased, accentuated, or split.

FIRST DEGREE OF ATRIOVENTRICULAR BLOCK Phonocardiographic evidence of atrial activity (sounds, murmurs) occurs earlier in regard to the 1st sound. If tachycardia is present, such murmurs may even become mid- or early diastolic. Thus, they may coincide with the opening snap of the mitral valve, with a 3d sound, or with the early diastolic murmur of mitral stenosis Unusual auscultatory rhythms may arise in this way.

Wolff-Parkinson-White Syndrome. Only a few phonocardiograms have been published to date. The interval Q-1st sound is normal; the 1st sound has a normal magnitude (Fig 11-22B). The 2d sound is neither split nor delayed. A 3d sound may be recorded. These data may be interpreted as indicating that (1) there is no bundle branch block (in the normal sense), (2) the P-R interval is only apparently shortened, (3) AV valves closure occurs at a normal distance from the P wave, in spite of the so-called *delta wave.*

BUNDLE BRANCH BLOCK

MODERN CONCEPTS OF VENTRICULAR ACTIVATION

The bundle branch block concept rests upon the knowledge of the process of ventricular activation *which takes place in the conducting* tissues of the heart, originating in the SA node, spreading *through the atria to the AV node,* the bundle of His and its two stems, and finally *reaching the myocardial* fibers through the subendocardial Purkinje network

When one of the branches of the bundle of His fails to conduct the stimulus, the order of ventricular activation is modified and certain elec-

the right or the left bundle branch is involved but also upon the severity of the lesion and the degree of conduction disturbance

According to studies of Sodi Pallares et al (1956), the first part of the ventricular myocar*dium to be activated is the interventricular septum,* which is no longer considered as a syncytial mass, but rather as *two separate portions, separated by a "barrier," in which the muscle fibers are diversely oriented with multiple synaptic connections,* in addition, these septal fibers have different polarities

The greater part of the septum belongs to the left ventricular myocardium, so that it forms the entire posterobasal aspect of the septum, which is completely devoid of right ventricular fibers. Thus, *the left ventricle encroaches upon certain areas of the endocardial surface of the right ventricle,* and an electrode placed at this point may actually *record left ventricular* potentials. The right ventricular component of the septum represents only *a minor fraction of its entire mass.*

The interventricular septum is activated from both the right and left endocardial surfaces *The left bundle branch is responsible for the activation of the entire left septal surface, as well as for most of the septum proper, whereas the right branch supplies a very small portion of this structure*

Since the left ventricular septal mass is greater than that pertaining to the right ventricle, it is obvious that the resultant vector *is directed from* left to right

The beginning of ventricular activation takes *place at the middle third of the septal surface,* and spreads from left to right, anteriorly and upwards The last points to be activated are the *anterobasal portions of the right septal surface*

The right surface of the septum is normally activated *0 01 sec after the left, whereas the last* portions are activated 0 03 sec later (Fig. 11-23A).

The initial septal vector is responsible for the small Q wave which is usually recorded in the leads overlying the left ventricle, and which is due to activation of the left *septal* mass This process

is initiated at the left ventricular endocardium and spreads toward the septal fibers at the base of the anterior papillary muscle of the right side of the septum, which at this level is probably still formed by the left ventricle.

The late activation of the basal portions of the septum is due to the scarcity of the Purkinje network at this level. It probably contributes to a great extent to the third cardiac vector (so-called "final vector"), although this is variable from one individual to the other.

Following the initial septal activation, the depolarization process spreads to the free walls of both ventricles perpendicularly, from the endocardium to the epicardium. Studies of Prinzmetal et al (1953) confirmed by Sodi Pallares (1956) have demonstrated that approximately two-thirds of the subendocardial aspects of the free walls of both ventricles are simultaneously and almost instantaneously activated, having practically no electrocardiographic representation. The potentials obtained in this area are similar to those recorded in the ventricular cavities, this portion of the myocardium was designated as the *electrical endocardium*, since from the standpoint of cardiac activation, it merely represents an extension of the cavity. The spread of excitation through the electrical endocardium is extremely rapid, having an approximate speed of 2,000 to 4,000 mm/sec. This is explained by the deep penetration of the Purkinje fibers into this part of the cardiac muscle.

The activation of the free wall of the ventricles is responsible for the second cardiac vector, which is primarily due to the predominance of electrical forces of the left ventricle, ten times greater than those of the right ventricle, the latter being insignificant from the standpoint of the vectorial analysis of the electrocardiogram in normal individuals (Fig. 11-23B).

This second cardiac vector is generally of great magnitude, is directed toward the left, posteriorly and downwards, and is seldom influenced by the right ventricle (this may occur in cases of extreme right ventricular hypertrophy). The predominance of the electrical forces of the left ventricle in cardiac activation explains the counterclockwise rotation of the normal vectorcardiogram in the horizontal plane.

The process of activation varies according to the degree of block. Thus, it becomes important to distinguish between complete and *incomplete bundle branch blocks.* This concept was established on the basis of experimental studies (Rodriguez and Sodi Pallares), by comparing the electrocardiograms obtained in dogs with various degrees of bundle branch block, and those of a human being's tracing with

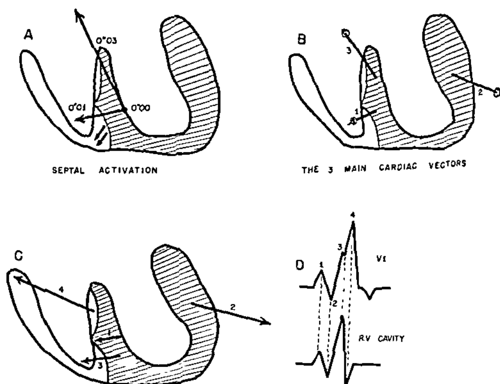

Fig. 11-23. A Septal activation. B The three main cardiac vectors C and D. Schematic representation of the four vectors resulting from ventricular activation in right bundle branch block, and the corresponding deflections in lead V_1 and in the right ventricular cavity.

similar configurations. It was observed that the *complete section* of one of the branches of the bundle of His was followed by a remarkable increase in the *duration* of the QRS interval and by a considerable delay in the intrinsicoid deflection, with secondary T-wave changes over the homolateral ventricle, in addition to a prolongation of electrical systole. These changes were characteristic of the complete type of bundle branch block. If instead of making a complete section, the upper part of *the interventricular septum* (*where the bundle branch crosses this area*) was compressed, it was observed that for short periods of time, QRS complexes were recorded similar to those of the previous experiment, the latter became progressively normal, with an intermediate stage during which a configuration similar to that of complete bundle branch block was obtained, although of shorter duration, these were designated as *incomplete bundle branch blocks.*

Notwithstanding the number of objections to the concept of bundle branch block in man, especially that of its septal mechanism, the above configurations represent, in the majority of cases, various degrees of conduction disturbance in one of the branches of the bundle of His causing ventricular asynchronism. This concept has been confirmed experimentally, pathologically, by intracavitary tracings and precordial leads, and by mechanical recordings showing ventricular asynchronism. Studies of Sodi Pallares on the mechanism of septal activation and experimental bundle branch block have contributed a great deal to a better understanding of this problem, confirming and extending knowledge of these conduction disturbances.

VENTRICULAR ACTIVATION IN BUNDLE BRANCH BLOCK

Right Bundle Branch Block. In all degrees of right bundle branch block, including the complete type, the wave of excitation crosses the *left septal* mass, which forms the majority of the septum, following the normal pathway with no change either in direction or velocity (1,000 to 1,200 mm/sec). However, there is a *late arrival* of the wave of *excitation* to the right side of the septum, with a considerable delay (0.06 *sec instead* of 0.01 to 0.02 sec) after the activation of the left side. This conduction delay is due not to uniform slowing of the wave of excitation *in* the entire septal mass, but rather to slower progression in a small area of the myocardium which is very close to the right surface, forming a "barrier" which separates the regions normally supplied by the left bundle branch from the area activated by the right branch. This has been proved experimentally by Sodi Pallares et al (1956) using bipolar leads, with the electrodes placed very close to one another, and including the intramural potentials.

From a vectorial point of view, four main vectors can be schematically identified in right bundle branch block representing the sequence of ventricular activation in these cases (Fig. 11-23C, D).

Vector 1 corresponds to the *normal septal vector,* since this phase of the activation process is unaltered in right bundle branch block, and determines the small Q waves in leads overlying the left ventricle, as well as the small initial positive deflection obtained both in the cavity of the right ventricle and over its epicardial surface.

Vector 2 represents the *activation of the free wall of the left ventricle* and is responsible for a small S wave recorded in the *right ventricular* cavity and over the right ventricular *epicardium,* since it is directed from right to left.

Vector 3 corresponds to the *powerful septal forces which are directed from left to right in the lower part of the septum,* and which develop when the wave of excitation crosses the barrier between left and right septal masses with a considerable delay. This vector is of great magnitude, as it is due to a slow type of activation, and it is well known that the slower the velocity of the excitation wave, the more powerful are the corresponding vectorial forces. In view of its great magnitude, it partially neutralizes the previous one corresponding to the activation of the free wall of the left ventricle, and explains the small amplitude of these forces. The third vector is responsible for the right intracavitary R′ and for most of the initial segment of the right epicardial R′.

Finally, *vector 4* probably *represents a summation of the activation of the upper portions of the septum and the free wall of the right ventricle,* determining the peak of R′ over the right ventricular epicardium and that of S′ recorded in the cavity of the right ventricle.

Left Bundle Branch Block. In right bundle branch block, *it is difficult to d*[illegible] e [illegible] e [illegible] *from left to right,* as in normal individuals. Thus, it is *impossible* to detect the exact instant when the *activation* crosses the

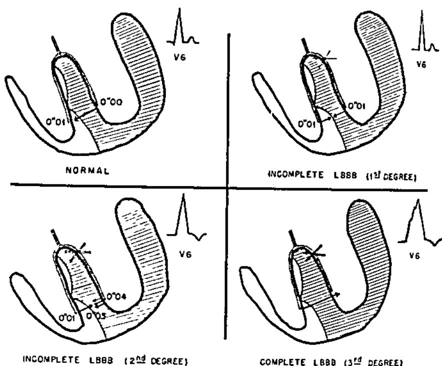

Fig. 11-24. Septal activation in the normal heart and in the three degrees of left bundle branch block with the corresponding ventricular complexes in the left precordial leads.

septal barrier However, this does not apply to left bundle branch blocks, in which different types of activation are observed in relation to the degree of this conduction defect. According to Rodriguez and Sodi Pallares, three types of left bundle branch block must be distinguished (Fig. 11-24):

1. *First degree* There is only a slight delay in the spread of the stimulus in the left branch of the bundle, resulting in a *late activation of the left septal surface*, without any change in the direction or speed of the excitation wave throughout the septal mass Since under normal circumstances, the activation of the left septal surface precedes that of the right by 0.01 to 0 02 sec, when a slight delay in the transmission of this wave occurs in the left branch (approximately 0 01 to 0 02 sec) both sides of the septum are simultaneously activated and consequently no Q wave is recorded.

2 *Second degree* In these cases, there is a greater delay of the conduction of the stimulus in the left branch, which nevertheless continues to transmit the impulse at a much lower speed Thus, the beginning of the left septal activation is recorded with a delay of 0.04 sec and is preceded by the right septal forces. *Septal activation occurs, therefore, in an opposite direction to normal, although only partially so.* The activation of the interventricular septum begins over the right septal surface and proceeds *from right to left;* if the barrier is transposed, the two septal forces will meet one another 0.04 sec later. It can be seen, therefore, that most of the septal activation proceeds from right to left, although this does not occur throughout the entire activation process, at the end of this process, late septal forces play a role and are directed from left to right. In this type of block, the Q wave, representing the normal first septal vector, disappears; there also is a slurring of the upstroke of R over the left ventricular epicardium. This represents the initial inverted activation of the septum (from right to left) and coincides with the initial r wave in the left ventricular cavity

3 *Third degree (complete left bundle branch block)*. In this type, the left branch is completely interrupted and is functionally incapable of transmitting the excitation wave. *The right branch activates the entire septal mass in an opposite direction to normal, i e., from right to left.* Septal depolarization is a comparatively slow process and takes place at an average speed of 300 mm/sec, which is similar to that of the spread of activation in the myocardial fibers themselves. This alone, however, does not explain the great delay of activation on the left side of the septum as compared

with the right (approximately *0.07 to 0.08 sec*)

According to *Sodi Pallares* (1956), the inverted activation of the interventricular septum *is retarded* at ... ually there is a delay at the ba ... w. ... is ... in ... opposite direction to that normally ... finally, the third delay occurs upon arrival of the activation wave at the left septal surface, which *acts as a second* barrier These points of delay explain *both the widening* of the QRS complexes and the slurring and notching of its various *components* which are characteristic of the complete left bundle branch block In all degrees of left bundle branch block, notwithstanding the marked *alterations in septal activation (which is not only delayed but often completely inverted in direction)*, the activation of the *free wall* of the left ventricle remains unchanged, although it begins later than normal, because of the delay that occurs in the interventricular septum

It has not been possible to confirm the above-mentioned concept of these partial types of left ventricular conduction defect by the vectorcardiographic analysis of the incomplete types of left bundle branch block In cases with electrocardiographic signs suggestive of incomplete left bundle *branch block, the horizontal plane VCG has shown a counterclockwise rotation*

THE ELECTROCARDIOGRAM IN BUNDLE BRANCH BLOCK

The general characteristics of the bundle branch blocks consist of *widening of the QRS* complexes *with slurring and notching of its various waves, delay of the intrinsicoid deflection in leads corresponding to the homolateral ventricle, prolongation of electrical systole, and secondary T-wave changes* It is to be emphasized that in addition to the characteristic *contours of the* electrocardiogram, the practical diagnosis of right or left bundle branch block requires certain data for a *more precise recognition* of *those conduction* defects, such as a *supraventricular* pacemaker, a P-R interval above 0 12 sec, and a typical configuration in the precordial leads Thus, the *diagnosis* of bundle branch block *cannot* be made in the *presence of complete* AV block, on the other hand, a P-R interval below 0 12 sec with a widened QRS complex usually *corresponds to* the Wolff-Parkinson-White *syndrome. A* complete set of precordial leads usually *permits* a precise *identification* of the bundle branch involvement, which is often difficult *on* the basis of the standard leads alone, especially in cases *of left bundle branch block in vertical hearts*, or right bundle branch blocks in *horizontal* hearts.

All types of bundle branch block may be *permanent* or *intermittent, in* the latter group are included cases in which the conduction defect *is transient,* with normal and aberrant *QRS complexes recorded in the same tracing.*

In some instances, the *electrocardiogram* may show alternating complete and incomplete bundle branch block, a fact in favor of the general concept of the *incomplete types of* conduction defect.

Complete Right Bundle Branch Block. In right *bundle branch block*, the initial septal vectors are directed from left to right (as *in the normal heart)* and the main abnormality *occurs in the final vectors. The study of* the unipolar, epicardial, and intracavitary potentials in right bundle branch block has led to a better understanding of the changes *observed* in standard and precordial leads

Intracavitary leads in right bundle branch blocks *were recorded by* Sodi Pallares et al. *(1948b), in* dogs as well as in human beings, and the configurations obtained corresponded to those calculated by the vectors of cardiac activation. Thus, in the right ventricular cavity, rsR'S' *complexes were recorded,* whereas *in the left ventricle,* the tracing *was essentially a QS wave* with notching and slurring of the descending limb (Fig. 11-25).

An important point to remember is that a part of the free wall of the right ventricle *corresponding to the trabecular zone is very thin* and rarely exceeds 2 mm, *leads* V_2 *and* V_3, which usually *overlie this area,* record potentials closely *resembling those of the right* ventricular cavity. This configuration is generally rsR'S', which *is explained* by the direction and magnitude *of the main* vectors ... ndle branch ... reference to ... of the free wall of the right ventricle *corresponding to leads* V_1 and V_2, the configuration is rsR', *with a notching* of the upstroke of the R' wave This shows the great delay *in the intrinsicoid deflection* over the right ventricular activation which occurs in right bundle branch block

The r and s waves correspond to vectors *1 and* 2 and coincide with the two *initial intracavitary* deflections The initial portion of R' is due to the

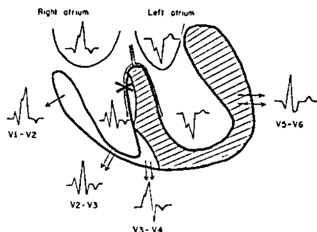

Fig. 11-25. Intracavitary and epicardial potentials in right bundle branch block.

third cardiac vector, which is the second septal vector This is demonstrated by the fact that the notching of the epicardial R′ is simultaneous with the peak of the intracavitary R′ (Fig. 11-23C, D). Finally, the peak of the epicardial R′ marks the arrival of the wave of excitation on the surface of the right ventricle and corresponds to the right intracavitary s wave. In other portions of the right ventricle corresponding to precordial leads V_3 and V_4, RS complexes are obtained with a notch on the ascending limb of the R wave This deflection is also partially due to low septal vectors located in the right portion of the septal mass, since this configuration cannot be explained on the basis of the above four vectors This has been emphasized by Sodi Pallares, who called attention to the fact that these R waves disappear in infarctions of the lower part of the septum

Over the epicardium of the left ventricle, qRS complexes are recorded, the initial negative deflection is due to septal activation from left to right, the R wave represents the activation of the free wall of the left ventricle (vector 2), and the S wave is generally widened and slurred, corresponding to vectors 3 and 4, which point away from the exploring electrode

In right bundle branch block, as shown above, the main abnormalities are those of the *late vectors*, which explains the slurring at the end of the QRS complexes in lead I and left precordial leads and the late R in aVR and in the right precordial leads, since the first vectors are directed from left to right, as in normal individuals, the q waves are present in lead II and over the left precordium, whereas the right precordial leads usually show an initial positive deflection.

On the basis of these data, the configuration of the various leads in right bundle branch block is easily understood

STANDARD LEADS. The QRS complexes show (Fig. 11-28A) notching and slurring with a duration of 0.12 sec or more, a widened S wave in lead I, usually smaller than the preceding R wave, is one of the main characteristics of this type of block; the q wave is usually present in this lead but may not be observed in certain cases. In lead III, the main deflection of the QRS complex varies according to cardiac rotation, it is negative in the horizontal hearts and positive in the vertical hearts. Several associated factors may change the configuration of the right bundle branch blocks in standard leads, particularly ventricular hypertrophy, myocardial disease, and the electrical position of the heart On the basis of the variations in configuration of the QRS complex in these leads, Bayley and Wilson et al. (1932) described several varieties of right bundle branch block which were subsequently thought to have different prognostic implications (Wilhus et al, 1941)

From a practical standpoint, the most common variety of right bundle branch block is the so-called *Wilson type of block* or *wide* S_1 *variety* It is characterized in lead I by a small initial q wave followed by a distinct, narrow R wave and a wide slurred S wave, with a positive T wave. In lead III, there is an rS complex or a deep Q wave with upright T in the horizontal heart, whereas in the vertical heart, the main QRS deflection is positive in lead III and is followed by a negative T wave. This variety of right bundle branch block is found in several types of heart disease, especially in chronic coronary insufficiency, but it may also occur in apparently normal individuals

The so-called *rare type of right bundle branch block* shows a small r in lead I (which may be absent in some cases), followed by a deep and wide S wave, while in lead III, the main QRS deflection is positive. The T wave in these leads is in the opposite direction of the QRS complex This type of right bundle branch block is often seen in right heart disease, suggesting the association of right bundle branch block with right ventricular hypertrophy.

A relatively rare variant of the Wilson type of right bundle branch block is the so-called *concordant inverted type*, in which wide S waves are present in the three standard leads (S_1, S_2, S_3)

Another type of right bundle branch block shows a wide, notched R wave in lead I, with or without an S wave and left axis deviation; the precordial leads are typical of right bundle branch block This type is not rarely encountered in cases of arteriosclerotic heart disease, but is especially common in Chagas' disease (Benchimol et al, 1954), where right bundle branch block is an exceedingly frequent finding However, vectorcardio-

graphic studies seem to indicate that these cases correspond to left bundle branch blocks associated with extensive septal and inferolateral infarctions The standard leads in right bundle branch block also show secondary changes of the repolarization process, with asymmetric T waves in the opposite direction of the major deflection of the QRS complex, thus, they are usually positive in lead I, in view of the marked widening of the S wave, and negative in lead III The electrical axis of the T wave (AT) is usually deviated to the left, as opposed to the right axis deviation of the QRS complex.

UNIPOLAR LIMB LEADS The configuration of aVL and aVF varies according to the electrical position of the heart, although in aVR there is always a late, slurred R wave (Fig 11-28A). This deflection is due to the late activation of the right ventricle from left to right, upwards and anteriorly (vector 4), in the direction of the right arm The QRS complexes are similar to those obtained in the right atrial cavity, whereas those of aVL and aVF resemble the left ventricular epicardial leads

PRECORDIAL LEADS In the right precordial leads (V_1 and V_2), the ventricular complexes are usually of the rsR' type with variations in the amplitude of the deflections from one case to another, involving particularly the first two waves of the QRS complex Occasionally, the S wave does not reach the base line and the configuration becomes rR' *The peak of the R' wave corresponds to the arrival of the wave of excitation over the right ventricular epicardial surface and is always delayed* Very often, there is a notch on the ascending limb of R' which marks the end of septal activation and the beginning of depolarization of the free wall of the right ventricle (Fig 11-23C, D), this was demonstrated by simultaneous recordings of precordial and right ventricular intracavitary leads

Since the beginning of septal activation is unchanged in right bundle branch block and is directed from left to right, the QRS complexes are almost always initially positive However, the absence of an initial r wave in V_1 does not necessarily represent an associated anteroseptal necrosis, it may be due to either a perpendicular direction of the first vector to lead V_1, or an enlarged right atrium which transmits its potential to lead V_1

With reference to ventricular repolarization, secondary inversion of the T wave is often seen, with a depressed S-T segment in leads V_1 and V_2

In the left precordial leads (V_5 and V_6), the QRS complexes are usually of the qRS type, similar to lead I, with a wide and slurred S wave (Fig 11-28A) In the absence of an associated left ventricular hypertrophy, there is no delay in the intrinsicoid deflection The T waves are generally positive, if they are negative, this suggests

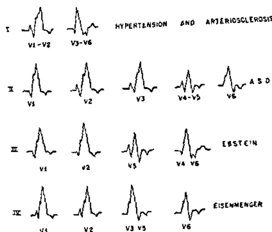

Fig. 11-26. Right bundle branch block in various types of heart disease (precordial leads).

myocardial ischemia or left ventricular hypertrophy.

In the intermediary points over the precordium (between leads V_1 and V_2), it is not unusual to record QRS complexes which resemble those of the right intracavitary leads (rsR'S'), probably corresponding to the thin trabecular zone of the free wall of the right ventricle In leads V_3 and V_4, an RS configuration is frequently obtained with a notch on the ascending limb of the R wave These waves are probably due to the low septal vectors pertaining to the right ventricular portion of the septum, as previously described (Fig. 11-25)

In the following types of heart disease with right bundle branch block, certain configurations of the precordial leads are often of diagnostic importance (Fig. 11-26):

1 In *arteriosclerotic* and *hypertensive heart disease* it is not unusual to record qRS complexes from leads V_3 to V_6, suggesting that the potentials of the hypertrophied left ventricle are transmitted to all leads which are to the left of V_3

2. In *atrial septal defect* (ASD), qR complexes are often obtained in lead V_1, because of right atrial enlargement, whereas the remaining precordial leads (V_2 to V_6) show right ventricular potentials, initially (V_2 and V_3) according the potential variations or the free wall, then those of the trabecular zone (V_4 and V_5), and finally those of the right side of the septum (V_6).

3. In *Ebstein's disease*, the potentials of the right atrium (qR) are recorded in leads V_3R, V_1, V_2 and occasionally extend to other precordial leads The left ventricular potentials

(qRS) are recorded in leads V_4 to V_6. Only occasionally are the right ventricular *potentials* obtained from the trabecular zone *in lead* V_3. Thus, in Ebstein's disease, the dominant electrocardiographic signs are those due to the right atrium and left ventricle, with a *limited* area of right ventricular complexes over the precordium.

4. In *Eisenmenger's syndrome*, leads V_3 *to* V_6 *reflect the potential variations of the lower* part of the septum, whereas leads V_1 and V_2 record *rsR' complexes* from the free wall of the right ventricle. Left ventricular *configurations* (qRS) are occasionally seen in lead VF.

Complete Left Bundle Branch Block. *When the left branch of the bundle of His is incapable of transmitting the cardiac stimulus, the entire septum is activated from right to left and the initial vectors become definitely abnormal. As a result, the q wave disappears in all leads which reflect the potentials of the left ventricle. In addition, there are an increased duration and a change in configuration of the QRS complexes, which become widened, slurred, and notched.*

These abnormalities can be attributed to the three main points of delay in the spread of the *stimulus* throughout the septal mass, as previously discussed with reference to cardiac activation in left bundle branch block.

A comparison of the unipolar epicardial configuration with the intracavitary leads is important in order to understand and interpret the standard and precordial leads. According to the experimental work of Sodi Pallares et al. (1950), in the intracavitary lead of the *left* ventricle, the form of the QRS complex varies from one point to another, in the lower part of the cavity, RS complexes are obtained, whereas the upper posterobasal portions show a qR configuration. The presence of a q wave in those leads is presumably due to the first *septal vector*, which is oriented from right to left, downwards, and slightly anteriorly; it is also possible that the lower part of the right aspect of the septum may contribute toward this deflection. This configuration is important for the diagnosis of infarcts involving the middle third of the septum, since in these cases, instead of RS complexes in the lower part of the left ventricular cavity, the tracing shows qR deflections resembling those of the posterobasal intraventricular leads. The S wave, which may be recorded in the cavity of the *left* ventricle, is probably due either to the activation of the upper part of the septum or to that of the free wall of the left ventricle.

In the cavity of the *right* ventricle, the configuration of left bundle branch block is essentially negative (QS), with notching and slurring of the QRS complexes.

Certain aspects of the epicardial leads in relation to the intracavitary potentials need further discussion (Fig. 11-27A). In the epicardial leads over the right ventricle, the R waves are often absent from V_1 to V_4, in view of the fact that the right-to-left septal vector is of great magnitude and neutralizes those of the free wall and the lower septal portion of the right ventricle. In the leads over the left ventricle (V_5 and V_6), the ascending limb of the R wave is probably due to the spread of the stimulus through the barrier, whereas the slurring of the "plateau" of the QRS complex corresponds to the activation of the septum from right to left; finally, the last peak of the

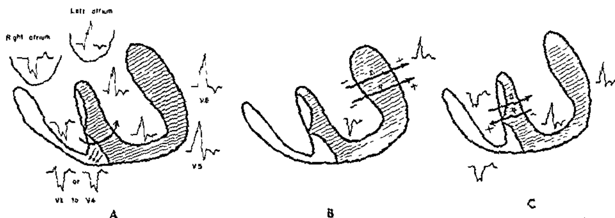

Fig. 11-27. A. Intracavitary and epicardial potentials in left bundle branch block. B. Ventricular repolarization in the normal heart. C. Ventricular repolarization in left bundle branch block.

R wave is due to the depolarization of the free wall of the *left ventricle*. Actually, it is not *known exactly where the septal activation ends* and that of the free wall of the left ventricle begins.

STANDARD LEADS. The *QRS complexes* are notched, slurred, and *widened, with a duration of* 0.12 sec or more (Fig. 11-28B). *There are no q or S waves in lead I*, and the mean electrical axis of the QRS complex (ÂQRS) is deviated to *the left from 0 to −75°. In rare cases*, the electric axis is *within normal limits, and under unusual* circumstances, a right axis deviation may be *present*.

The presence of a q wave in lead I would suggest a previous septal infarction, peri-infarctional *block, respiratory* variations of cardiac position, or *other factors, including right ventricular hyper*trophy.

The variations of *ÂQRS* in left bundle branch block are due *to several factors, such* as left ventricular hypertrophy, the location and extension of coexistent myocardial lesions, and especially the position of the heart in the chest. The *concordant* types and those with right axis deviation are generally found in *vertical hearts*.

The T waves are asymmetric and opposed to the major deflection of the QRS *complex, this is also observed with reference to the S-T segment*.

UNIPOLAR LIMB LEADS. The patterns obtained in these leads are essentially dependent upon the electrical position *of the heart*. Since left bundle branch block is mostly seen in horizontal hearts, lead aVL records left ventricular potentials and is similar to leads *I*, V_5, and V_6. *In some of these cases, a small q wave may be recorded in these leads in the absence of anteroseptal infarction. In lead aVF, the* ventricular complexes are of the *rS* or *QS* types, a fact which is *not due to myo*cardial *necrosis. Lead aVR* shows variable configurations (rS, QS, QR), according *to the position* of the QRS axis, and generally *resembles* the right atrial intracavitary lead.

In the unusual cases occurring in *vertical hearts*, aVF records left ventricular *potentials* and aVL faces *the right* ventricle, whereas aVR is *variable* and depends upon the degree of right axis deviation. *This* electrical position is *responsible for* patterns simulating *right bundle branch block* in the standard *leads, although* the *precordial* configurations *are typical and diagnostic*.

PRECORDIAL LEADS. In leads V_5 and V_6 corresponding to the *left ventricle*, essentially positive QRS complexes are obtained with an *initial, slurred* R wave of variable *amplitude (Fig. 11-28B)*. Following this deflection, there is *always a notched* plateau which extends to *the peak of a* rapid and *delayed intrinsicoid* deflection; in certain cases, these complexes *assume* an M-shaped configuration. There is, as yet, no *complete agreement as to the correct interpretation of the pattern*.

It is to be emphasized that in hearts with *marked clockwise rotation*, these QRS complexes are *observed only* in lead V_7 (or farther to the left), which may suggest an associated *right* ventricular enlargement. The T waves *are negative*, with an S-T segment depression and an upward *concavity of the S-T segment*; these repolarization changes are secondary *to the QRS abnormality*.

In *leads* over the right ventricle (V_1 and V_2), *the tracing does not* show remarkable *changes*, as it begins with a small r wave and ends with a *wide and* deep *S wave. The persistence* of the initial r wave *in the left bundle branch block, in* the presence of an inverted septal activation, is probably *explained* by early *activation of* the free wall of the right ventricle, in addition to that of the lower portions of the septum pertaining to *this ventricle. Very often, however*, this small *r wave disappears*, and *QS* complexes *are recorded* in the right precordial leads, suggesting *the presence* of anteroseptal infarction. In these cases, the negativity *is explained by a neutralization* of the *lower* septal *vectors* and *those of the free wall by the more powerful* septal forces directed from right to left. The T waves *are positive* in these leads, with elevated S-T segments.

Ventricular Repolarization in Left Bundle Branch Block. Under normal *circumstances*, the repolarization *process of the free wall of the left ventricle dominates* that of the interventricular septum, and explains the negative T wave in the ventricular *cavity with an upright* deflection over the epicardial surface. This is because, in *man*, repolarization proceeds in an opposite direction to that *of depolarization* (Fig. 11-27C and D). *In left bundle* branch block, septal repolarization is greater than that of the free wall and is directed from right to left, although the *vector is conventionally represented in the* opposite direction. This explains the negative T wave both in the cavity and over the left ventricular *epicardium*. Consequently, *septal repolarization* is *mainly* responsible for *the T-wave changes* in left bundle branch block.

INCOMPLETE BUNDLE BRANCH BLOCK

The *concept of "incomplete"* bundle branch block *presupposes* a delay in conduction through one of the branches of the *His bundle*, although the *excitation wave* is not entirely

arrested as in the "complete" types of block. Thus, the activation of each ventricle in the incomplete bundle branch blocks proceeds through its corresponding branch, though with a variable degree of delay.

This interpretation was accepted following the investigations of Wilson and Herrmann, which were later confirmed and extended by Sodi Pallares (1950), in addition to the clinical observation of tracings similar to those experimentally obtained

The fact that both clinically and experimentally, continuous tracings were obtained showing QRS complexes intermediate in configuration between normal records and complete bundle branch block (Fig 11-32A) seems to confirm the actual existence of incomplete bundle branch block, which has been such a controversial subject among the various investigators.

From the morphologic standpoint, these tracings resemble complete bundle branch block, although the duration of the QRS complexes is less than 0.12 sec (usually between 0.10 and 0.12 sec). However, Sodi Pallares attaches greater importance to the morphologic

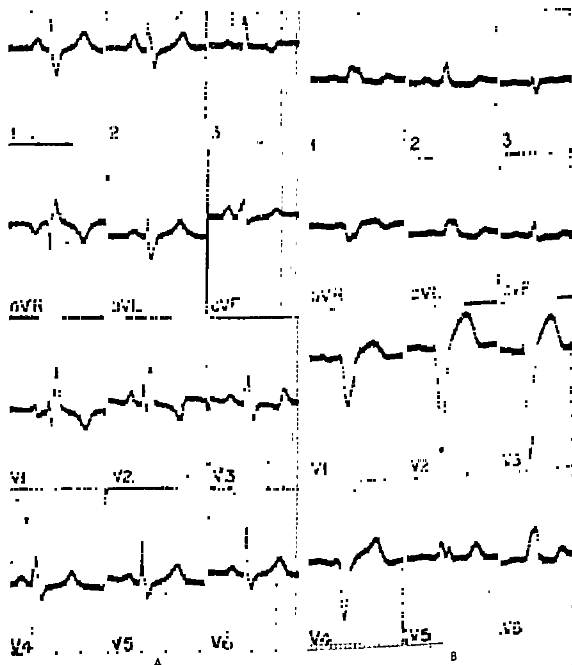

Fig. 11-28. A. Complete right bundle branch block in a 29-year-old patient with interatrial septal defect B. Complete left bundle branch block in a 60-year-old patient with arteriosclerotic heart disease.

criteria than to the delay of the intrinsicoid deflection, accepting as incomplete bundle branch blocks even cases with a *normal* QRS duration (*less than* 0.10 sec).

Incomplete Right Bundle Branch Block. This type includes electrocardiograms with an rsR' configuration in the right precordial leads, with variable amplitudes of the individual deflections, and a total duration of the QRS complexes below 0.12 sec. Although the intrinsicoid deflection is inscribed with a delay of 0.04 to 0.05 sec, the marked delay observed in incomplete right bundle branch block *is not seen in these cases. In the standard leads,* the tracing *may be normal,* although there often is a slurred S wave in lead I and a late wide R wave in lead III.

This type of electrocardiogram is frequently observed in normal individuals, although it is especially common in diseases affecting the right heart (atrial septal defect, tricuspid insufficiency, etc.). Although Sodi Pallares et al. (1950) consider this configuration as due always to a right bundle branch conduction defect, Kossmann et al. (1950) admit the possibility of a late activation of the crista supraventricularis of the right ventricle, both in normal individuals and in some persons with right ventricular hypertrophy.

From a practical standpoint, it is obvious that not all tracings with this configuration actually represent incomplete right bundle branch block. However, it is extremely difficult to distinguish the true incomplete right bundle branch block from similar tracings which correspond to normal variants, or those due to right ventricular hypertrophy, although several criteria have been suggested to differentiate these conditions. The most important practical contribution to this problem has been that of *vectorcardiography* in clarifying certain aspects of the rSR' configuration in V_1.

Incomplete Left Bundle Branch Block (Fig. 11-24). The *first-degree left bundle branch block* is characterized by an absence of q waves in leads V_5 and V_6, which is not in itself sufficiently diagnostic, since this may occur in normal individuals with vertical heart and a clockwise rotation. However, the presence of an initial slurring of the R wave in these leads is of greater diagnostic importance, since it represents bilateral septal forces which neutralize each other. The T waves are either normal or slightly decreased in amplitude.

In *second-degree left bundle branch block*, septal activation is partly inverted, the majority of the septal mass being activated from right to left. Only a small portion of the left side of the septum is activated by late forces directed from left to right. In these cases, Q waves are absent in leads V_5 and V_6 and there is a slurring of the entire upstroke of the R wave. The duration of the QRS interval is slightly greater than that of first-degree bundle branch block, and the T wave becomes negative because of the inverted direction of septal repolarization (Fig. 11-32B).

In contrast to the incomplete right bundle branch block, which may occur in normal hearts, in the majority of cases, incomplete left bundle branch block denotes organic heart disease with left ventricular hypertrophy. The occurre [illegible] and in [illegible] nating [illegible] important evidence in favor of the incomplete bundle branch block concept, which is still denied by some authors.

BUNDLE BRANCH BLOCK AND VENTRICULAR HYPERTROPHY

The configuration of right bundle branch block, especially of the incomplete type, is often seen in certain types of right heart disease, such as atrial septal defects, tricuspid insufficiency, etc., and has been described by Cabrera and Monroy as evidence of *diastolic overload* of the right ventricle. Although this is true in most cases, it should be emphasized that similar electrocardiograms may be observed in normal hearts and in cases of true right bundle branch block. The distinction between these three conditions is difficult from an electrocardiographic standpoint, and it is often necessary to base the interpretation upon clinical data and on other abnormalities of the tracing (P pulmonale, Lewis index, right axis deviation, etc.). *Vectorcardiography* is of great help, because the orientation of the loop in the horizontal plane is frequently diagnostic and differs in right ventricular hypertrophy from that in normal hearts and in right bundle branch block.

It is well known that left bundle branch block usually coexists with left ventricular hypertrophy. According to most authors, the latter is practically inferred in the presence of this type of conduction defect; however, there are

a few exceptions to this rule, such as the case shown in Fig. 11-24B.

In the presence of associated bundle branch block, the classical electrocardiographic criteria for the diagnosis of ventricular hypertrophy may not apply, because of the altered pathways of ventricular activation. In such instances, the recognition of ventricular overload may be extremely difficult.

A review of the criteria proposed by a number of authors, which so far have been accepted, has shown that they cannot be used in many cases.

Many of these patterns appear in *experimental blocks*, and occasionally in a variety of clinical cases, in which the diagnosis of coexistent ventricular hypertrophy cannot be made unequivocally. On the other hand, certain cases of *transient bundle branch block* with suggestive evidence of associated hypertrophy have not exhibited any of the diagnostic criteria of ventricular overload following the restoration of normal conduction.

At present, it appears that the best criteria for the diagnosis of ventricular hypertrophy associated with bundle branch block are the following.

1 *Diagnosis of right ventricular hypertrophy in the presence of right bundle branch block*

a. Signs of right atrial enlargement

b. Right axis deviation exceeding +120°

c. Presence of RR′ in leads to the left of V_3 (this is considered as evidence of right ventricular dilatation)

d. Deeply inverted T waves in V_1, V_2, and V_3

Although, from a statistical standpoint, deep S waves in leads I, V_5, and V_6, or an R′ exceeding 10 mm in V_1, occur more frequently in cases of associated right ventricular hypertrophy, these signs may also make an appearance in many cases of isolated right bundle branch block.

2. *Diagnosis of left ventricular hypertrophy in the presence of right bundle branch block*

a. Signs of left atrial enlargement (in the absence of mitral stenosis)

b. R waves of high voltage and a delayed intrinsicoid deflection in V_5 and V_6 (0.05 sec)

c. Deep S wave preceding an R′ in V_1 and V_2

d. QRS axis deviated upwards and to the left in the frontal plane

e. Presence of q waves in leads I, V_5, and V_6

Other minor signs, which may be useful in some cases, are the early transition in the precordial leads and the presence of T-wave inversion in leads V_5 and V_6

3. *Diagnosis of left ventricular hypertrophy in the presence of left bundle branch block*

As previously stated, the presence of left bundle branch block in itself is considered evidence of associated left ventricular hypertrophy in view of the high statistical incidence (approximately 95 per cent) of left ventricular enlargement in cases of left bundle branch block. Nevertheless, the following signs are highly suggestive of left ventricular hypertrophy in the presence of left bundle branch block:

a. Sokolow-Lyon index above 35 mm

b. White-Bock index above +18 mm

c. Marked left axis deviation of the QRS complex, with right axis deviation of the T wave

d. Tall R waves in the left precordial leads with a tendency to the disappearance of the "plateau"

e. Signs of left atrial enlargement (an indirect sign, although one of the most important diagnostic criteria of associated left ventricular hypertrophy)

Under these circumstances, it is very difficult to identify right ventricular hypertrophy for several reasons, including the fact that these cases usually exhibit biventricular hypertrophy associated with left bundle branch block.

However, vertical electrical position of the heart, clockwise rotation, and leftward displacement of the transitional zone in precordial leads with S waves in V_6 and V_7 are highly suggestive of coexistent right ventricular hypertrophy (Laham, 1951, 1952).

From a *vectorcardiographic* standpoint, the association of right ventricular hypertrophy and right bundle branch block has been described (Burch et al., 1953, Wolff et al., 1953) as showing a displacement of the QRS loop anteriorly and to the right and as maintaining the classical VCG characteristics of right bundle branch block (delayed terminal appendage) [Fig. 11-36(2)]

Left ventricular hypertrophy in right bundle branch block displaces the loop so that it as-

rather a *more superior* orientation as compared with its position in uncomplicated right bundle branch block (Grishman and Scherlis, 1952, Burch et al., 1953, Massie and Walsh, 1960).

An interesting type of left ventricular hypertrophy with *terminal delay in intraventricular* conduction has *been* described by Grishman and Scherlis (1952). *In* these cases, the ECG displays *a widened* QRS complex, with wide, *slurred S waves in* V_6, marked left axis deviation, and secondary *S-T segment and T-wave* changes.

The VCG in *these cases shows the* typical *signs of left ventricular hypertrophy,* with a *delay in the terminal* segment of the afferent portion of the *QRS loop,* which is oriented to *the right, posteriorly,* and superiorly.

INTERMITTENT BUNDLE BRANCH BLOCK

Experimentally, a complete bundle branch *block* pattern may be *obtained* by direct percussion of one of the branches *of* the bundle of His (this is more easily *obtained* in the right *bundle branch), and serial changes of* the tracing are *recorded. It is interesting to note then that as the conduction* defect improves, the degree of *block progressively* decreases until *normal conduction is* finally restored. It is conceivable, therefore, that in the *presence of an* organic lesion of one of the *branches* of the *bundle* of His, the *occurrence of* an attack of tachycardia, or any other *aggravating* factor of *the* conduction defect, *may* lead to a transient *block of* the impulse through the damaged bundle branch. Thus, intermittent bundle branch blocks are *probably more common than they appear to be statistically,* and would probably be more *frequently* recorded if *serial* tracings were *obtained in* the initial stages of the organic bundle branch lesions. Nevertheless, numerous *cases* of *transient bundle* branch block have been published in the literature (Bentchumol, 1944, 1945), *demonstrating* that *this is not a rare finding in clinical cases*.

It was *thought* at first that this represented a purely *functional disturbance,* however, it is now *considered* to be *due to lesion of the* conduction tissues, frequently denoting *advanced* cardiac disease. The *majority* of the so-called "functional" bundle branch blocks is observed in the course of supraventricular tachycardia or atrial flutter or fibrillation. Although *some* patients with this type of block do not appear to suffer from any cardiac disease, *it is* difficult to rule out minor *lesions of the* conduction tissues leading to *fatigue of* the bundle branch with a decrease *in its conduction* capacity in the presence *of a functional strain.* Many factors have been *described* as capable of precipitating *these* types of block. Thus, changes *of vagal tone* or of heart rate, hypoxia, heart failure, toxic processes, etc., have been considered.

Although *changes* in vagal tone may indirectly influence intraventricular conduction, it appears that this increased tone is not *directly* ...sible for the prolonged inhibition of con- [illegible]

factor, have been described (*Vessell,* 1951). There was a critical *rate for the appearance of* block, and this *often disappeared following a* slight decrease *of rate. In other instances, the* bundle *branch block appears on effort or following some* factor which temporarily overloads the heart in the presence of advanced *pathologic* changes (*usually due to* coronary arteriosclerosis).

In these cases, the different involvement *of* the two branches *leads to a difference of their refractory periods.* However, *a normal* intraventricular *conduction* is still compatible with a permanent increase in the refractory period predominating in one of the branches of the *bundle of His.* The *conduction* defect only appears *following the influence* of certain *factors, which increase the refractory period or inhibit conduction completely.*

Cases have *been described in which bundle* branch *block appeared in the course of heart* failure and *disappeared as soon as cardiac* compensation was obtained. *Other* instances

Fig. 11-29. Electrocardiogram of a 65-year-old male with complete right bundle branch block and anterolateral infarction: deep Q waves are recorded in left precordial leads, with the typical right bundle branch configuration maintained in leads V_1 *and* V_2.

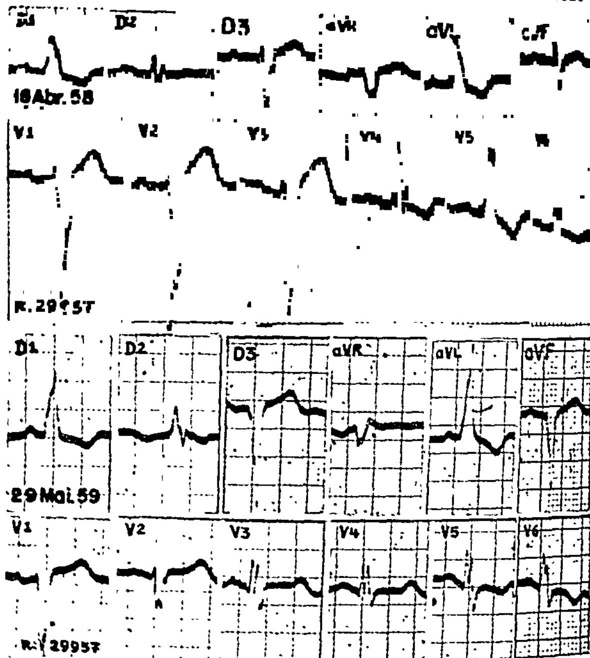

Fig. 11-30. Electrocardiogram of a 60-year-old patient with arteriosclerotic heart disease, showing complete left bundle branch block in the upper tracing. Bilateral internal thoracic artery ligation was performed for the relief of angina pectoris in June, 1958. In May, 1959, the patient sustained an acute coronary thrombosis; the ECG recorded 4 weeks later (lower tracing), shows deep S waves not previously present in leads V_5 and V_6, probably because of the transmission of the left intracavity potential (RS) to the exploring electrode through the area of necrosis.

have been reported in the course of *digitalis intoxication* (Benchimol, 1944) It is possible that these cases may be due to a vagal influence, although it is believed by most authors that a direct toxic effect on the conduction tissue, such as occurs in cases of *myocarditis*, is probably responsible.

In clinical practice, when an intermittent type of bundle branch block is recorded, it often appears or disappears following physical effort, amyl nitrite inhalation, or atropine injection.

Vagal stimulation obtained by ocular compression may cause the block to disappear, as in Fig 11-31. This is not a direct vagal effect upon the bundle branch, but rather an indirect

of the bundle branch system.

...

according to the site of necrosis (in the ... in the free walls of the ventricles). These studies have shown that abnormal Q waves in leads V_1 and V_2 *denote an infarct of the middle third of the septum*, whereas similar deflections in V_3 and V_4 indicate *low septal infarctions*. Deep Q waves in leads V_5 and V_6 are *characteristic signs of involvement of the free wall of the left ventricle*. When the infarct is located in *the free wall of the right ventricle or in the upper part of the septum*, there are no definite electrocardiographic signs that can be considered *diagnostically significant*. Some types of infarction included in this classification correspond to a combination of those previously described.

It should be *emphasized* that cases of right bundle branch block with *right atrial dilatation* often exhibit in leads V_1 and V_2 a qR configuration with a delayed *intrinsicoid* deflection, which *may lead to the erroneous diagnosis of right bundle branch block complicated by anteroseptal infarction*. The differential diagnosis *is established by the clinical data, by the progressive ST-T changes, and possibly by the presence or absence of Q waves in left precordial leads, since in cases of midseptal infarction the disappearance of the initial septal vector results in the absence of Q waves in left precordial leads.*

In the presence of left bundle branch block, the electrocardiogram seldom shows signs diagnostic of myocardial necrosis. This is explained by the fact that in left bundle branch block, the *initial vectors of ventricular activation are fundamentally* altered in direction and the *septum is depolarized in a* direction opposite *to the normal*, i.e., *from right to left*, causing an abnormal, initial positivity in the left ventricular *cavity*. Thus, *it is impossible to diagnose a necrosis of the free wall of the left ventricle because the cavity* potentials are transmitted to the *epicardial surface through* the "electrical window" and r waves are re-

Fig. 11-31. Electrocardiogram of a 67-year-old female with hypertensive and arteriosclerotic heart disease and angina pectoris of 2 years' duration. Note the initial complexes in each lead showing a normal intraventricular conduction This was obtained by a slight slowing of the cardiac rate as a result of ocular compression. The last QRS complexes in every lead exhibit a configuration of complete left bundle branch block In lead II, ventricular premature beats with a bigeminal rhythm are recorded.

corded instead of the typical Q waves which denote infarction. However, in the early stages of the coronary attack, the diagnosis of myocardial infarction associated with left bundle branch block may be suggested by ST-T and T-wave changes due to injury and ischemia, especially in cases that have a suggestive clinical history and in the presence of serial tracings.

When the infarct involves the *septal mass*, the initial negativity of the right ventricular cavity is transmitted to the left and is recorded through the infarcted area in left precordial leads, and occasionally in lead I. Thus, the presence of a Q wave in leads I, V_5, and V_6 in a case of left bundle branch block usually denotes an associated *septal infarction* (Fig 11-33D). The observation of RS complexes in leads V_7 and V_6 was suggested as a sign of *lateral wall infarction* in cases of left bundle branch block because of the recording of left intracavitary potential (RS) over the epicardial surface of the left ventricle through the area of myocardial necrosis (Fig. 11-30). It must be emphasized, however, that this configuration may also be recorded at the transitional zone if the latter is displaced to the left, as in a horizontal heart with a clockwise rotation.

It should be emphasized that Q waves may be present in leads I, V_7, and V_6 in cases of left bundle branch block without myocardial infarction. There are several possible interpretations for these initial negative deflections. (1) recording of left atrial potentials in horizontal hearts with marked clockwise rotation; (2) associated right

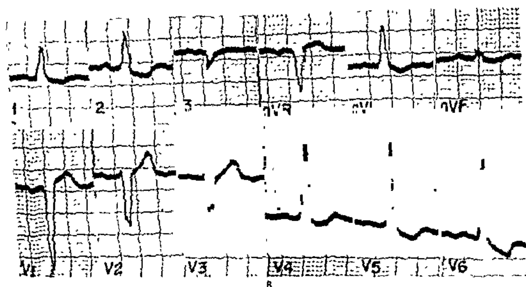

Fig 11-32 A *Left* bundle branch block Note in lead I a transitional complex with the configuration of incomplete left bundle branch block, followed by a QRS complex with normal intraventricular conduction (the last complex in lead I). In the remaining leads the ECG shows incomplete left bundle branch block. ventricular hypertrophy; (3) right intraventricular conduction defect (Laham, 1952).

Certain cases of left bundle branch block show Q waves in leads I, V_5, and V_6 *in the* absence of myocardial infarction. This is because of one of the following possibilities: (1) recording of left atrial potentials over the *precordium in* horizontal hearts with marked clockwise rotation; (2) associated right ventricular hypertrophy; or (3) right intraventricular conduction defects.

Cabrera and Friedland (1953) called attention to the importance of a late notching of *the S or QS* wave in leads V_3 and V_4 as a *strong* indication of myocardial necrosis in the

presence of left bundle branch block (Fig. 11-33E).

Sodi Pallares et al. (1957) described eight varieties of infarction complicated by bundle branch block, which could be distinguished electrocardiographically on the basis of the modern concepts of ventricular activation and the identification of the intracavitary potentials. It was shown by these authors th[illegible] involvemen[illegible] block, could be sugge[illegible] tary potentials (RS) in precordial leads V_5 and [illegible] possible to [illegible] ment and in cases with extension into the [illegible] wall of the left ventricle.

Most pathologic studies have confirmed the electrocardiographic criteria for the diagnosis of myocardial infarction complicated by left bundle branch block.

THE VECTORCARDIOGRAM IN *BUNDLE BRANCH* BLOCK

Vectorcardiography has unquestionably played an important role in the better understanding of many obscure aspects of the ECG, particularly with reference to the intraventricular conduction defects.

Nevertheless, the subject of conduction defects has not yet been completely clarified, and there are still many controversial opinions regarding electrogenesis and the correct interpretation of many ECG tracings, as well as VCG loops. Adequate experimental data, in addition to electrovectorcardiographic correlation, are still lacking. Lately, however, important contributions have been published in the literature on this subject, and many problems have appeared requiring future investigation.

The VCG *is very useful* in the diagnosis of the more advanced forms of bundle branch block. Interpretation of the lesser degrees of these conduction defects is still controversial, and, at present, it is difficult to distinguish certain cases of ventricular hypertrophy from the so-called incomplete types of bundle branch block.

As previously mentioned, the electrocardiographic diagnosis of bundle branch block is based upon certain findings, such as atrioventricular conduction, abnormal slurring and notching of the QRS complexes, and a late R wave *in the unipolar leads facing the ventricle* on the side of the blocked bundle branch.

Atrioventricular conduction cannot be demonstrated in the VCG, *it is necessary to record* the ECG for this purpose. With reference to notching and slurring, the VCG is a more adequate tracing, since it distinguishes the true from the false *types of slurring*. *True slurring* is due to a slow inscription of the spatial vectors, and it is observed in the various planes, the *false types of slurring* result from the perpendicularity of certain portions of the VCG loop in relation to one of the planes, and are therefore limited to this *plane*.

Finally, the late R wave corresponding to the ventricle with delayed activation is shown in the VCG by a loop which points *toward this* ventricle. *As a rule, the main* vectorcardiographic features of bundle branch block are the slow inscription of certain portions of the loop, the direction of *the initial part of the* loop, and *frequently the type of rotation* in the horizontal plane (Grishman and Scherlis, 1952).

In Complete Left Bundle Branch Block. The *main VCG features* of complete left bundle branch block are as follows (Fig. 11-34):

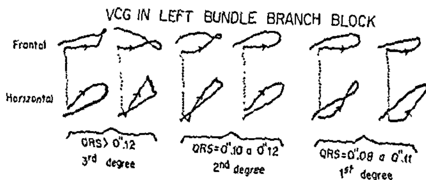

Fig. 11-34.

1. Changes in the spatial QRS loop. In the *horizontal plane,* the initial portion of the loop (Q loop) decreases, and is slowly inscribed, oriented usually forward and slightly to the left; in some cases, however, it is directed posteriorly and to the left, and very rarely anteriorly and slightly to the right. Whatever its initial direction, the QRS loop, sometimes after a sharp angulation, is rapidly inscribed posteriorly and to the left (R loop) with a clockwise rotation, which is the main VCG feature of this type of block.

The long axis of the loop usually lies between −30 and −60° in the horizontal plane. In the afferent limb, or more frequently in its middle portion, there is evidence of conduction delay, as shown by the closer proximity of the time markings. At this point, there is an irregularity of the loop, constituting a "plateau," the duration of which is proportional to the degree of block (Fig. 11-35).

Occasionally, the VCG in the horizontal plane is characterized by a "figure-8" type of rotation, with an initial counterclockwise direction followed by a clockwise inscription; in these cases, the Q loop is usually directed anteriorly and to the left.

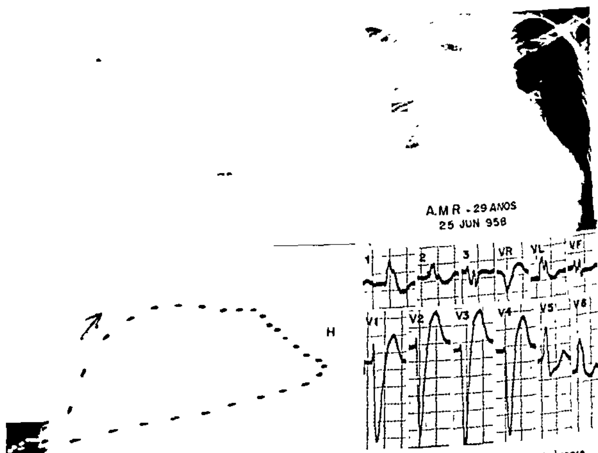
The QRS sÊ usually fails to close prior to the inscription of the T sÊ loop, this is because it does not return to its point of origin, so that the J point is deviated to the right and anteriorly, resulting in an ST vector pointing in the same direction.

In the *frontal plane,* the QRS sÊ loop of the VCG is inscribed counterclockwise (with very rare exceptions), to the left, and superiorly. The loop is usually open, with an ST vector pointing downward and to the right.

In the *sagittal plane,* it is important to note the clockwise rotation of the loop, with its main axis pointing posteriorly and slightly superiorly or inferiorly. The loop fails to close as in the other planes, with an ST vector pointing anteriorly and slightly inferiorly.

2. Spatial T Loop (T sÊ). The T sÊ loop is usually oriented opposite the QRS sÊ loop, to the right, anteriorly and superiorly or inferiorly.

In Incomplete Left Bundle Branch Block. The vectorcardiographic criteria of incomplete left bundle branch block are much less precise



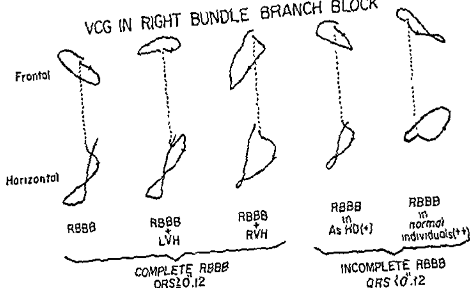


Fig. 11-35. Complete left bundle branch block in a 29-year-old male with Chagas' heart disease. The VCG shows the typical clockwise rotation in the horizontal plane with a delay in the middle portion of the loop.

\+ Arteriosclerotic heart disease
\++ This type of loop with QRS duration > 0".12 may complete RBBB and is often observed in chronic Chagas' heart disease

Fig. 11-36.

than those of the complete type. Very often, the VCG in incomplete left bundle branch block is similar in configuration to that of complete left bundle branch block, with the exception of its duration (less than 12 sec) and the lesser degree of slowing observed in the middle portion of the loop (first- and second-degree left bundle branch block) (Fig 11-34).

In certain instances, the slowing of the middle portion does not occur, but the loop is inscribed in a clockwise direction in the horizontal plane, this is an important distinguishing feature from simple left ventricular hypertrophy.

The QRS sE loop in the horizontal plane is *frequently inscribed to the left and posteriorly,* [illegible]

[illegible] portion or not. In these cases, the loop has a characteristic figure-8 type of configuration with a *slow inscription of its initial portions,* with or without an additional delay in the middle portion of the loop

Finally, in certain instances of incomplete left bundle branch block, the middle portion of the *horizontal QRS loop* shows either a slight slurring or a *counterclockwise rotation,* although a certain delay in the initial portion of the loop is observed, it is difficult to distinguish these types of VCG from those of left ventricular hypertrophy.

In Right Bundle Branch Block. *The initial portion of the* QRS sE loop is normally inscribed, i.e., to the right and anteriorly, since the initial vectors of ventricular activation remain unchanged in this type of conduction defect. The most important feature of the loop is its *terminal* portion, which is *slowly inscribed,* with an *irregular contour constituting* an appendage which in the horizontal plane is directed anteriorly and to the right (Fig 11-36) The general aspect of the loop varies in form and direction.

Two main types have been pointed out One was described by Grishman et al. (1938), with a QRS sE loop inscribed to the left and posteriorly and a counterclockwise rotation in the horizontal plane followed by a delayed terminal appendage (Fig. 11-36(1)). These loops correspond to the ECGs of the so-called *atypical forms of right bundle branch block,* and are often found in *chronic Chagas' heart disease,* AV communis, and other cardiac *conditions.* A second type of VCG in right bundle branch block has been emphasized by Cabrera et al. (1958), with the QRS sE loop in the horizontal plane *showing* an initial clockwise rotation,

followed by a counterclockwise inscription, and a preterminal delay often resulting in a figure-8 configuration [Fig. 11-36(2)]. This type is often seen in coronary heart disease.

The T loop is usually opposed to the delayed terminal appendage, and its abnormalities are less conspicuous than those of left bundle branch block. The vectorcardiographic distinction between *complete* and *incomplete right bundle branch block* is made solely on the basis of the duration of inscription, since there are no significant differences in configuration of the respective VCG loops.

The VCG has been found to be the most useful in distinguishing incomplete right bundle branch block from other tracings with an rsR' configuration in lead V_1, which correspond to either normal hearts or slight degrees of right ventricular hypertrophy.

ETIOLOGY

Coronary heart disease is undoubtedly the main cause of bundle branch block, either as an isolated factor or in association with arterial hypertension. One of the branches may be damaged by an *acute infarction*, followed by fibrosis, or by a slow and progressive *ischemia* due to chronic coronary insufficiency.

Bundle branch blocks may be found in the absence of any type of apparent organic heart disease; this is much more common in right than in left bundle branch block.

Left bundle branch blocks occur mostly in hypertensive or arteriosclerotic heart disease and in aortic valvular disease, especially in *calcific aortic stenosis* and in *syphilitic aortic insufficiency*. Less common causes are classified in Table 11-2.

Right bundle branch blocks are observed in normal persons and in a variety of organic heart diseases, and are thus commonly found in clinical practice.

In normal individuals, right bundle branch block is usually of the incomplete type, decreasing during the Valsalva maneuver and increasing during the Muller maneuver. The elec-

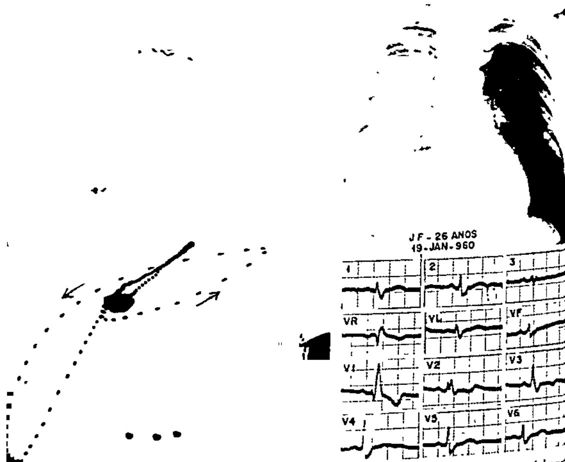

Fig 11-36(1). Complete right bundle branch block in a 26-year-old patient with Chagas' heart disease. The mean spatial QRS axis is at −150°. The VCG shows a counterclockwise rotation in the horizontal plane, with a terminal delayed appendage pointing rightward and anteriorly.

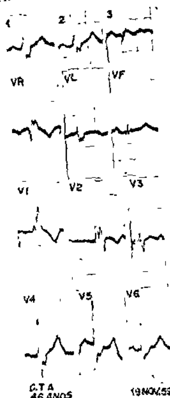

Fig 11-36(2). Right bundle branch block with ÂQRS at 180° in a 46-year-old patient. The VCG displays an initial clockwise rotation of the loop in the horizontal plane, followed by a counterclockwise rotation and a delay in the terminal portion

trocardiographic and *vectorcardiographic* features are usually similar to those found in pectus excavatus and in certain *atrial septal defects* without pulmonary hypertension

In younger patients, the main causes of right bundle branch block are *congenital heart disease*, *rheumatic heart disease*, and *Chagas' disease*.

With reference to rheumatic heart disease, right bundle branch block is usually found in the presence of mitral and tricuspid lesions. In these instances, P-wave changes diagnostic of biauricular enlargement are *usually present*, or atrial fibrillation, in addition to other characteristic changes of rheumatic heart disease.

In *pure mitral stenosis*, which exhibits a double-peaked R wave in V_1, there is usually *a moderate* degree of right ventricular enlargement.

In many Latin American countries, a common cause of right bundle branch block is

a complete type of right bundle branch block, with left axis deviation as a very common finding [Fig. 11-36(3)]. In serial tracings, other electrocardiographic abnormalities are often associated, such as ventricular premature beats and various types of AV block.

In congenital heart disease, right bundle branch block is frequently recorded (Table 11-3), especially in *atrial septal defects*, either as an isolated finding or associated with other cardiac malformations.

In isolated atrial septal defects, according to most authors, right bundle branch block is an *evidence of diastolic overload* of the right ventricle; *in such instances, the conduction defect* is either complete or, more frequently, incomplete, with right axis deviation, and, contrary to the situation in coronary cases, very seldom shows a counterclockwise rotation. The P-wave changes are usually more marked than those *observed in coronary insufficiency*, although of a lesser degree than *those exhibited* by mitrotricuspid patients.

The problem of right bundle branch block, and especially that of a double-peaked R wave in right precordial leads, is of great interest

TABLE 11-2. ETIOLOGY OF BUNDLE BRANCH BLOCK

Type of BBB	*Type of patient*	*Cause of block*
Right	Young	Congenital heart disease Rheumatic heart disease Tricuspid lesions Chagas' disease
	Older	Arteriosclerotic heart disease Cor pulmonale: Acute Chronic
	Exceptional	Toxic factors Infections Tumors Gummas, etc.
Left	With *coronary* insufficiency	Arteriosclerotic heart disease with or without arterial hypertension Calcific aortic stenosis Syphilitic aortic insufficiency
	Exceptional	Tumors Gummas Chagas' disease Myocarditis, etc

in the study of congenital heart disease, having important implications from the standpoint of both electrogenesis and differential diagnosis

In older patients, the appearance of right bundle branch block is usually due to coronary arteriosclerosis. In such instances, the block is usually complete, with left axis deviation and counterclockwise rotation. Lead I usually exhibits a qRs configuration (with a slurred S wave), and lead III shows an rSr′ configuration.

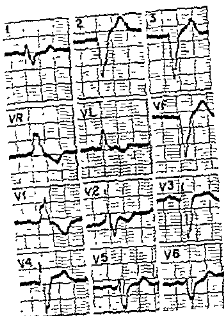
Another common cause of right bundle branch block is *cor pulmonale*, in both its acute and chronic forms. Under these circumstances, AQRS is usually deviated to the right, with clockwise rotation and signs of right atrial enlargement, in addition to other classical signs of these conditions

Bundle branch blocks of any variety may appear in several forms of myocarditis, in thyrotoxicosis, in myocardial disease of unknown etiology, in myocardial tumors, cysts, gummas, trauma, *etc.* In addition, they may be caused by the *toxic effects* of several drugs, such as digitalis, quinidine, and Pronestyl, and also may appear in certain endogenous intoxications, such as hyperpotassemia due to acute or chronic renal insufficiency (Schlesinger and Benchimol, 1956).

CLINICAL FINDINGS

There are no symptoms that are diagnostic of bundle branch blocks, the clinical manifestations that may occur are due either to the etiologic factor involved or to an unrelated clinical syndrome.

There are, however, certain signs which may result from ventricular asynchronism and, therefore, are directly related to the bundle branch block. These signs are (King, 1928) a double cardiac impulse, a muffled and prolonged 1st sound, and a split 2d sound A presystolic gallop rhythm and a midsystolic apical murmur, if present, are not related to the block.



Under special circumstances, the physical signs may suggest the presence of bundle branch block. The most important clinical finding is a distinct and wide splitting of the 2d heart sound (Cossio et al., 1940).

Clinically, *left* bundle branch block may be suggested if there is a presystolic gallop rhythm without heart failure and *a split 2d heart sound with a late aortic component*, so that the reduplication is accentuated by expiration In *right* bundle branch block, there is a *more distinct splitting of the 2d sound with a marked delay in the pulmonic component*, which is highly suggestive Left bundle branch block indicates in most patients a diffuse type of heart disease, whereas right bundle branch block is not necessarily a sign of serious cardiac involvement.

PROGNOSIS

Bundle branch blocks were formerly considered to have an ominous prognostic significance; it is now believed that it is not the conduction disturbance itself but the etiologic factor involved, especially the nature and degree of the myocardial damage, which dictates the prognosis in each case (Schreenivas et al).

Although it is not rare to find bundle branch block as the sole manifestation of cardiac disease (in certain cases with a long survival), these conduction defects usually indicate an extensive myocardial damage, which in most patients is a result of arteriosclerotic heart disease.

masc. 34 years

Fig. 11-36(3). Complete right bundle branch with left axis deviation (-100°). The VCG in the horizontal plane shows a clockwise rotation of the QRS loop with its major portion oriented to the right and anteriorly. Note slight *counterclockwise rotation in the apical portion of the loop. Conduction delay is present in the afferent portion of the loop* The VCG is diagnostic of right *bundle branch block and right ventricular hypertrophy* Note that the initial portion of the *efferent loop is directed leftward and slightly posteriorly, suggesting an associated left ventricular hypertrophy, particularly in the presence of marked left axis deviation.*

TABLE 11-3 BUNDLE BRANCH BLOCK IN CONGENITAL HEART DISEASE

Type of BBB	*Cyanotic*	*Noncyanotic*
Right Ri		with severe pulmonary hypertension
Left axis deviation	AV communis	Ventricular septal defects with mild pulmonary hypertension Ventricular septal defects with or without atrial septal defects
Left	Tricuspid atresia	Coarctation of the aorta Aortic stenosis Patent ductus arteriosus (rarely)

Right bundle branch block is usually considered to have a much less severe prognosis than left bundle branch block. Although this is true in most instances, one must consider each case from the clinical standpoint and not base the prognosis only on the type of bundle branch block.

Several investigators have attempted to determine the average survival time of patients with bundle branch block; some of them have found it to be relatively short. This would seem to indicate an unfavorable prognostic significance of these conduction disturbances. However, more recent statistical studies not only have shown much longer survival periods, but also have pointed out how difficult it would be to estimate how long patients can live with bundle branch block, because it is often impossible to determine the duration of the block prior to its recognition.

TREATMENT

There is no treatment of bundle branch block as such. Therapy must be directed toward the etiologic factors involved, when possible. Although there is no formal contraindication to the administration of *digitalis* in the presence of bundle branch block, if the conduction defect results from toxic effect of the drug, it is imperative to withdraw the medication, at least temporarily. *Quinidine* should be administered most carefully to these patients, under electrocardiographic control; administration should be stopped as soon as there is a further widening of the QRS complex or following the appearance of other types of conduction defect.

INTRAVENTRICULAR BLOCK

Under this designation, a series of intraventricular conduction disturbances has been described, in which the main branches of the bundle of His are not involved. The delay in activation occurs in the more distal segments of the conduction system or in restricted areas of the myocardium in the free ventricular walls. According to Segers, the absence of anatomic lesions of the branches of the bundle of His in certain cases exhibiting electrocardiographic changes which closely resemble those of bundle branch block suggests the possibility of a *focal block* with conduction delay in limited zones of the ventricular myocardium Because certain cases in which the EKG was characteristic of bundle branch block did not reveal, by electrokymographic studies, a delay in the onset of homolateral ventricular ejection, although a prolongation of the ejection period was observed, Segers suggests that the delay in the spread of the activation wave occurs in the lateral walls of the ventricle, representing what he has called *parietal block*. Other authors had previously described cases in which a conduction delay occurred in extensive areas of the ventricular walls at the distal ramifications of the conduction system Oppenheimer and Rothschild described cases with wide QRS complexes and low voltage under the designation of *arborization block*.

According to Grant, parietal block is due to disseminated lesions involving the anterior division of the left branch of the bundle of His; in these cases, the QRS complexes are not necessarily widened, the beginning of ventricular activation is normal, and the conduction delay occurs only in the lateral walls. This results in marked left axis deviation in view of the orientation of the terminal vectors, which are directed leftward and superiorly.

An electrocardiographic pattern showing deep S waves in leads II and III, exceeding the amplitude of the R waves, in the absence of S waves in lead I, has recently been described by Davies and Evans as due to a conduction disturbance in the peripheral branches of the left branch of the bundle of His. They attribute these lesions usually to ischemic changes and believe that the diagnosis of myocardial infarction is highly probable in patients with this type of EKG and with symptoms of cardiac pain.

When the focal lesion is more extensive and is localized in the subendocardial areas of the high anterolateral wall of the left ventricle, in addition to the involvement of the anterior division of the left branch of the bundle of His, resulting in left axis deviation, the initial portions of the QRS complex are also affected, and this has been called *peri-infarction block*, and is characterized by a wide Q wave which is associated with left axis deviation [Fig 11-36(4)].

The main electrocardiographic feature of peri-infarction block is the widening of the angle between the initial and terminal 0.04 sec

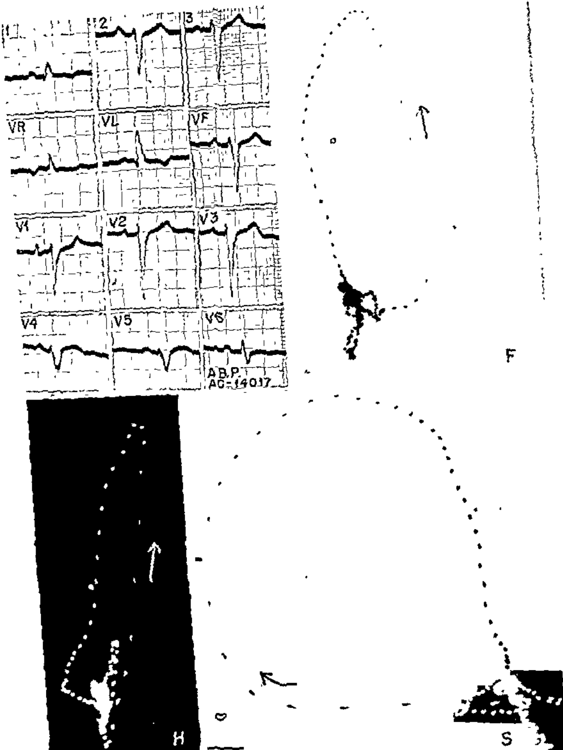

Fig 11-36(4). Focal *peri-infarction block in a 67-year-old male.* The ECG displays wide Q waves in leads I and VL *(high lateral infarction)* associated with left axis deviation *(−85°) and* a QRS *duration of 0.12 sec.* The VCG reveals a counterclockwise rotation *in the horizontal plane,* as well as *a conduction* delay in the terminal portions of the loop *in the three planes*

of the QRS complex. With rare exceptions, in the presence of left axis deviation, when this angle exceeds 100° the EKG is diagnostic of anterolateral peri-infarction block. This type of conduction disturbance was initially described in 1950 by First and coworkers, who interpreted it as being due to the involvement of extensive areas of the subendocardial portions of the ventricles and of the Purkinje network. Under these circumstances, the impulse spreads through the noninvolved myocardium around the infarcted area, and its conduction is delayed at this point.

Finally, a type of *diffuse intraventricular block* has been described that resembles left bundle branch block, with Q waves in left precordial leads.

These cases are apparently due to a diffuse conduction disturbance through the ventricular wall, resulting from left ventricular hypertrophy, diffuse myocardial fibrosis, quinidine toxicity, or hyperpotassemia.

GRAPHIC DATA IN BUNDLE BRANCH BLOCK

PHONOCARDIOGRAM

The 1st sound is *prolonged* and lasts more than 0.16 sec. It is frequently of low amplitude. *Splitting of this sound* has been described by several authors. However, this observation is not confirmed by "stethoscopic" tracings and should be attributed to either inadequate or different techniques. Ventricular asynchronism results in the delay of the contraction of one ventricle over that of the other of about 0.04 to 0.05 sec. This interval is too short for causing a splitting of the central phase of the 1st sound, which lasts from 0.06 to 0.08 sec. However, it causes prolongation of the sound in both right and left bundle branch block. If *left* ventricular hypertrophy and intraventricular block add their effects to that of *left* bundle branch block, the delay between the contractions of the two ventricles may reach 0.06 sec or more. Then, closing of the mitral valve (first valvular event of the left heart) takes place at the time of opening of the pulmonic valve (second valvular event of the right heart) because the normal isometric tension period (about 0.05 sec) lasts as long as the pathologic interval between the contractions of the two ventricles. The phonocardiogram then reveals *three groups of vibrations*. the first is due to tricuspid closure; the second,

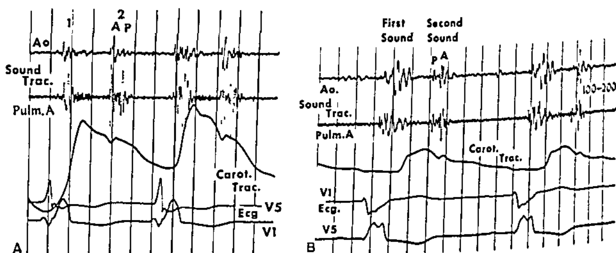

Fig. 11-37. A. Simultaneous phonocardiograms over the aortic (Ao) and pulmonic (Pulm. A.) areas, compared with carotid tracing and unipolar ECG chest leads. Time, 0.1 sec. The second component of the 2d sound is visible only in the pulmonic tracing and does not coincide with the incisura of the carotid pulse. Diagnosis: *right ventricular delay due to right bundle branch block*. M. Simultaneous phonocardiograms over the aortic (Ao) and pulmonic (Pulm. A.) areas, compared with carotid tracing and unipolar ECG chest leads. Time, 0.1 sec. The second component of the 2d sound is visible over both areas of the base and coincides with the incisura of the carotid pulse. The aortic 1st sound occurs later than the pulmonic 1st sound. Diagnosis: *left ventricular delay due to left bundle branch block*.

to pulmonic opening plus mitral closure; the third, to aortic opening. A *similar phenomenon*, with delay of right ventricular events, occurs when *right intraventricular block* and *right ventricular hypertrophy* add their effects to that of *right bundle branch block*.

It is probable that a new study by means of "*selective phonocardiography*," with its scanning of adjacent bands of sounds, will reveal different data, possibly including a "splitting" of the 1st sound. (The quotes are necessary because the 1st sound already presents a "physiologic" splitting when recorded in normal subjects in the band 240 to 460 cps.)

The 2d sound, being shorter, is constantly split in bundle branch block. In the case of *right bundle branch block*, as the pulmonic component *normally follows the aortic component of the 2d sound by* 0.02 *sec*, the 2d sound is widely split, and there is an interval of about 0.05 to 0.07 sec between the aortic and the subsequent pulmonic component (Fig. 11-37A). In the case of left bundle branch *block*, the opposite occurs. If there is only a slight delay of the aortic component, it will fall at the time of the pulmonic component (*no splitting of the 2d sound*). If, on the other hand, there is a severe delay, then the aortic component will *follow* the pulmonic component *by 0.02 to 0.04 (paradoxical splitting of the 2d sound, Leatham)* (Fig. 11-37B).

CAROTID TRACING, JUGULAR TRACING

The delay between the beginning of the 1st sound and the rise of the carotid pulse (usually about 0.05 sec) *is increased* and lasts from 0.07 to 0.08 sec in *left bundle branch block*. The incisura of the carotid pulse *coincides* in normal subjects with the main vibration of the *2d sound* (aortic component). In *left bundle branch block*, it coincides with *the 2d phase* of the split 2d sound (*aortic component*) (Fig. 11-37B). The rise of the carotid pulse has a normal relationship to the beginning of the 1st sound in *right bundle branch blocks*. The incisura has a normal relationship to the 1st phase of the split 2d sound (aortic component) in this type of block (Fig. 11-37A) *while the* pulmonic component occurs later.

In *right bundle branch block*, the study of the jugular tracing is of importance. *the peak of the V wave is markedly delayed* and occurs 0.08 to 0.14 sec after the end of the 2d sound (or after the 2d phase of the 2d sound, if this is split). In other words, the V wave, which usually occurs 0.08 to 0.14 sec after the 2d sound, has the same relationship to the pulmonic component (2d phase) of *this* sound, when it is split.

ELECTROKYMOGRAM

This method may be applied to the study of pulmonic or aortic pulsations. *In most cases*, it may be *applied to the study* not only of left ventricular but also of right ventricular contraction. Moreover, right atrial tracing is so deeply influenced by right ventricular contraction that the phases of right ventricular dynamics may be studied even by recording a right atrial border tracing. The best technique is that of recording simultaneously a *high left ventricular tracing* and a pulmonic tracing, then, a right ventricular (or right atrial) tracing with an aortic tracing.[2] The study may be completed by the simultaneous observation of the anterior (right ventricle) and posterior (left ventricle) surfaces of the heart. It should be kept in mind that while direct comparison of the two ventricles has a decisive importance, *comparison of one ventricle with one pulse (or of the aortic and pulmonic pulses)* is less significant on account of possible interaction of peripheral factors which may accelerate or delay the valvular events.

Normal time *relationships between the two* ventricles and the two large vessels were studied by the author and his coworkers (1948) and by Samet and coworkers (1950b). In spite of slight individual and phasic variations, it can be assumed that the two ventricles and the two large arteries present pulsations which succeed each other within 0.02 sec. The most *common* is the precession of the pulmonic pulse by 0.020 sec (Part 4, Chap. 8).

In about 30 per cent of the cases of *left bundle branch block*, left ventricular contraction and the aortic pulse are delayed over the

[2] If one has *only a pickup unit*, the study should be made in the following way: (1) aortic electrokymogram (EKy) plus sound tracings, (2) pul- ... of the carotid tracing *as timer is confusing* in these cases of bundle branch block because the carotid pulse is necessarily delayed in left bundle branch block.

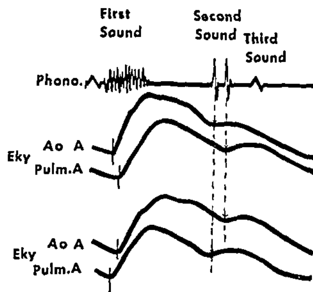

Fig. 11-38. Scheme of the electrokymograms of the aortic and pulmonary arches in right (above) and left (below) bundle branch blocks with ventricular asynchronism. (*From Luisada. Heart Beat Hoeber, 1953.*)

right ventricular and the pulmonic pulse by about 0.03 to 0.05 sec (Fig 11-38). If there is hypertrophy or intraventricular block of the left side, the delay is greater. Hypertension of the greater circulation increases the delay revealed by the rise of the pulse, decreases that revealed by the incisura.

In about 30 per cent of the cases of *right bundle branch block*, the right ventricular contraction and the pulmonic pulse are delayed over the left ventricular and the aortic pulse by about 0.03 to 0 05 sec (Fig. 11-38). If there is hypertrophy of the right ventricle or intraventricular block of the right side, the delay is greater. Hypertension of the lesser circulation increases the delay revealed by the rise of the pulse, decreases that revealed by the incisura. Systemic hypertension may partly neutralize the effect of right bundle branch block, so that the delay is less apparent.

In both types of block, a prolongation of the phase of isometric relaxation was observed A large percentage of cases of bundle branch block, whatever the side, seem to present a bilateral delay of contraction upon EKy studies Phonocardiographic studies reveal a much larger percentage of asynchronism than EKy studies.

CONDUCTION

The Wolff-Parkinson-White syndrome and other forms of preexcitation

EUGENE LEPESCHKIN

L. Wolff, J. Parkinson, and P. D. White described (1930) a syndrome which usually appeared in young persons with occasional paroxysmal tachycardia (but otherwise normal hearts) and was characterized by *a short P-R interval and a wide QRS complex* resembling bundle branch block. Many of these persons showed on other occasions normal QRS complexes with normal P-R intervals, the P-J interval to the S-T junction usually remaining the same length as in the aberrant complexes. Öhnell, who studied the syndrome extensively (1940), showed that it was caused by *premature excitation* of a part of the ventricle by the atrium, and introduced the term *preexcitation* to designate this as well as other less characteristic electrocardiographic patterns. In the typical pattern, the wide premature component of the QRS complex is of relatively low voltage and shows a distinct kink with the slender terminal portion of the QRS complex, which corresponds to normal activation of the ventricles through the AV node and is nearly identical in the normal and the aberrant complexes. In the vectorcardiogram, this premature portion usually moves two to three times more slowly than the rest of the QRS loop (Grishman and Jaffe, Wolff and Richman). The slow premature portion has been called by Segers et al. (1947) *the delta wave*, as it resembles the Greek letter Δ in configuration (Figs. 11-39, 11-40).

In some cases, not only the initial, premature portion of the QRS complex but also its terminal portion is wide and slurred, and the form of the QRS complex is identical with that of bundle branch block. This pattern appears when normal activation through the AV node is delayed or absent, and the ventricles are activated exclusively in the premature manner, directly from the atrium. In such cases, the P-R interval of the normally conducted complexes is usually prolonged (Blom) or the AV bundle is completely interrupted (Mahaim, Scherf et al.). This pattern was designated as *type F* by Öhnell, but in order to avoid confusion with the grouping according to the direction of the delta wave, it will here be called *complete preexcitation*. In other cases, the premature component of the QRS complex is of very short duration and may be hard to distinguish from a normal slurred onset of the R wave, the duration of the QRS complex in these cases is accordingly not prolonged beyond the upper normal limits (Fig. 11-41). This pattern results when the normal conduction through the AV node is especially rapid, and only a small section of the ventricles can be excited directly from the atria before the rest of the ventricular mass is excited through the normal conducting system. It is usually seen in persons with normally short P-R intervals, such as children or young women. Relatives of persons with this pattern also tend to show a short P-R interval (Koch). This pattern has been designated as *type A* by Öhnell but will be called here *rudimentary preexcitation*, to avoid confusion. A third atypical pattern, designated as *type E* by Öhnell, shows the usual slurred configuration of the QRS complex but *a long or normal P-R interval*, and is due to a delay in both the normal and the premature excitation of the ventricle, the P-R interval of the normally conducted beats is always prolonged (Mahaim, Koch,

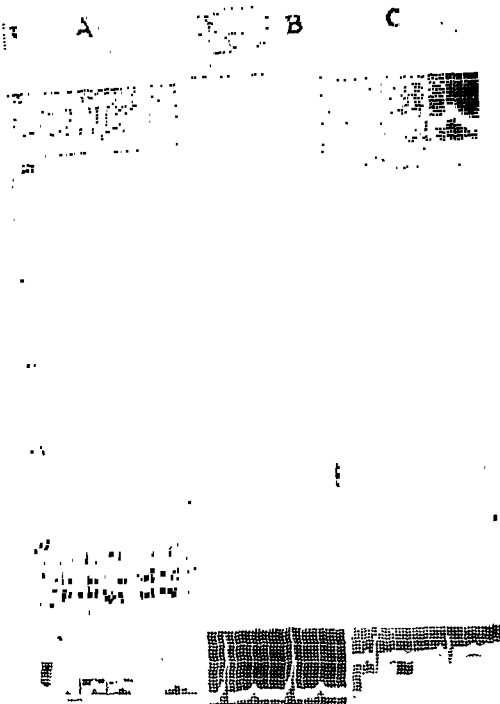

Fig 11-39 A Electrocardiogram of a 12-year-old girl *during* an attack of paroxysmal tachycardia *The P* waves follow the QRS complex and *are diphasic, but* mainly upright in leads I to III The QRS complexes are narrow, the *alternation in* amplitude of the R wave *is common* in *all* supraventricular tachycardias with *very high* ventricular rates. B. After termination of the attack, sinus rhythm *with type B* preexcitation is present. C After *medication* with quinidine, preexcitation *disappears The fusion of the T wave with the U wave is part of the* quinidine *effect.*

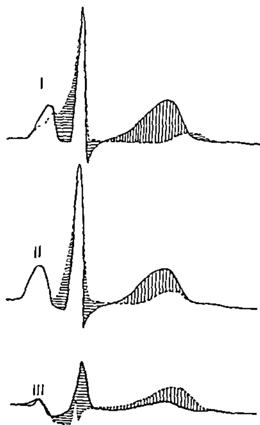

Fig. 11-40. The limb lead electrocardiograms of Fig. 11-39B are superimposed on corresponding leads of the same patient taken several weeks later when no preexcitation or quinidine effects were present. It can be seen that the increase in the positive area of the QRS complex (horizontal shading) is equal to the decrease in the positive area of the T wave and S-T segment (vertical shading).

Glushien and Goldblum, Pick and Katz). This pattern will be called *delayed preexcitation*.

According to the direction of the premature component of the QRS complex in the precordial leads, Rosenbaum, Hecht, Wilson, and Johnston distinguished two groups of cases. In "group B" this component is upright in the unipolar precordial leads V_3 through V_6 but inverted in V_1 (and sometimes also in V_2), the right, lower, and posterior portions of the thorax, and usually also aVF; in the frontal plane, this component shows usually left axis deviation but sometimes a normal axis. In this group, the highest negative voltage of this component was found in leads from the right atrium near the tricuspid valve and in the lower esophagus, while leads from the cavity of the right ventricle and the coronary vein showed a positive premature component (Grishman et al., Giraud et al.; Hecht et al., 1957). This indicates that the prematurely excited ventricular muscle is *on the posterolateral epicardial surface of the right ventricle, near the AV groove*. In group A, the premature component of the QRS complex is negative on the back but positive in leads V_1 through V_6 and usually also in aVF, so that its axis in the frontal plane is usually normal or deviated to the right, and only occasionally deviated to the left. In intracardiac leads, some cases of this group showed the same findings as in group B, and the difference in the configuration of leads V_1 to V_2 in these cases was therefore attributed to a different position of the heart (Grishman et al.). However, in cases of this group

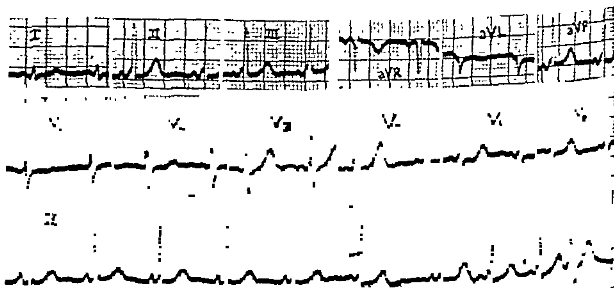

Fig. 11-41. Electrocardiogram of a 22-year-old woman with rudimentary preexcitation of type A, who complained of occasional rapid heart action. No electrocardiogram could be taken during the attack. The lower strip shows "concertina effect," leading to pseudonormalization during the pressor phase of the Valsalva maneuver and to increased preexcitation during the postpressor phase. One ventricular extrasystole appears at the end of the tracing.

which showed an *isoelectric* or negative premature *component* in leads I and V_6, this component was positive in the right atrium and ventricle, but *deeply negative* in the coronary vein, which is in contact with the posterior *aspect of the left ventricle near the AV groove* (Giraud et al.). It was, therefore, concluded that *this is the site of the prematurely activated portion of the ventricle*. Such cases constitute *less than 20 per cent* of all *persons* with the Wolff-Parkinson-White syndrome. In both groups, the subepicardial location of the prematurely excited section accounts for the low voltage and long duration of the premature component of the QRS complex, since the rapidly conducting Purkinje fibers do not penetrate to the epicardium

Holzmann and Scherf and, independently, Wood and coworkers suggested that the premature excitation of the ventricle by the atria could take place through an *accessory* bundle similar to that first described by Kent (1893) This bundle consists of nonspecialized muscle and can, therefore, be expected to conduct excitation *more rapidly* than the specialized thin muscle fibers of the AV node, whose function is to delay excitation of the ventricle. A subepicardial accessory muscle bundle connecting the posterolateral aspects of the right ventricle and atrium was actually found in two cases with the preexcitation syndrome (Levine and Burge, Lev et al), and three similar subendocardial bundles were found in another case (Wood et al.), in still another case, the connection was between the atrial and ventricular septa on the right side (Segers et al, 1947) All these cases belonged to group B A subepicardial connection between the *left atrium and ventricle* was found in two cases (Öhnell, Mahaim), and an additional case showed both a right-sided and a *left-sided connection* (Kimball and Burch) All these *cases belonged* to group A and showed a negative premature component in lead I; the electrocardiographic pattern accordingly is in keeping with the anatomic location of the aberrant pathway On the other hand, the incidence of this pathway in routine autopsies is no greater than that of preexcitation (Lev et al.)

However, in several persons who had shown preexcitation, *no* accessory bundle could be found despite careful histologic study (Soderstrom, Hecht et al, 1957) In these cases, another explanation must be sought Holzmann and Scherf suggested that preexcitation can be due to stimulation of an acquired irritable ventricular center by the stretching effect of atrial contraction; such a center could also be set off by the action potential of atrial fibers (Segers et al, 1947) As these effects would be great*est near the AV* border, especially if there is intimate contact between atrial and ventricular muscle fibers, as in the cases of Söderström and Langendorf et al., the localization of the premature component would be in keeping also with this hypothesis Stable preexcitation complexes were often seen to appear during cardiac catheterization, Giraud et al. found this in more than one-third of all catheterizations Prinzmetal et al (1952) could elicit such complexes most commonly by applying pressure, or a subthreshold electric current, to the inner surface of the ventricles through the atrium. In these cases, atrial contraction was probably transmitted mechanically through the catheter or the stimulating electrode. Preexcitation also could be elicited by injection of aconitine or epinephrine into the ventricular septum near the *AV* border (Frau and Maggi), and may also appear after intravenous injection of strophanthin (Vakil) or epinephrine (Fig 11-42) All these procedures increase ventricular excitability In all these cases, the complexes with short P-R interval and wide QRS complex usually showed transitions to ventricular parasystolic rhythms or coupled extrasystoles showing no relation to the P waves It is very difficult to decide in *a given* case whether true coupling of *the ventricular* complexes to the P *waves exists or whether* the relation between the wide QRS complex and the P wave is a fortuitous one Furthermore, there are many factors which may cause synchronization of P waves to the preceding QRS complexes (Rosenbaum and Lepeschkin), and the designation of *preexcitation* cannot be applied to *them True preexcitation* becomes probable *if the short P-R* interval remains *completely constant* during a series of beats *(Pick and Katz)*, but it can be proved definitely *only if this interval* remains con*stant even* in the presence of spontaneous or *induced variations* of the P-wave rhythm A *mechanical* coupling can be expected to pro*duce a rather* loose synchronization, since the *instant* when a given tension is exerted on the *ventricle* would vary with the stroke volume,

heart position, etc. An electrical coupling, on the other hand, would be much more constant, since the shape of the P waves and the sequence of activation of atrial muscle near the AV border show only insignificant variations.

A third hypothesis, advanced by Prinzmetal and coworkers (1952), is that the premature activation of the ventricle is due to accelerated conduction in part of the fibers of the AV node. Experiments considered as proof of this hypothesis are open to criticism (Sodi Pallares, 1956, Hecht et al., 1957). Furthermore, it would not explain the slow ascent of the premature component of the QRS complex, since premature activation of the rapidly conducting specific system would cause a rapid initial component

The incidence of the typical Wolff-Parkinson-White pattern is 0 02 to 0.04 per cent in children (Landtman; Vacheron), 0.07 to 0.1 per cent in apparently normal adults and in ambulatory patients (Hecht et al., 1957), and 0 16 per cent in hospitalized patients. This increased incidence with age and severity of disease, together with its appearance in infections or rheumatic heart disease, could be considered as favoring an acquired genesis of the syndrome The explanation of Pick and Katz, that any acquired factors which impair normal AV conduction would facilitate congenital aberrant conduction, does not seem plausible, since aberrant conduction takes place before normal conduction However, since conduction in aberrant anatomic pathways may be present only occasionally (Lyle), the increased incidence of aberrant complexes under abnormal conditions may be simply the result of the electrocardiograms being taken more often and in longer strips. On the other hand, the smaller incidence in children may be due to the short normal P-R interval, which may mask all or part of the aberrant conduction.

The fact that preexcitation was repeatedly found in two or more members of the same family (Öhnell; Koch; Hecht et al, 1957) is strongly in favor of a congenital origin of this anomaly, as are the occurrence of other congenital anomalies and the high incidence (0 7 per cent) of preexcitation in persons with congenital heart disease (Hecht et al, 1957) and the fact that preexcitation is twice as common in males as in females in all age groups (Vacheron; Lown et al.).

Increase of the heart rate, whether spontaneous or due to exercise, the Valsalva maneuver (Fig. 11-41), standing up, fever, atropine, amyl nitrite, or Banthine, usually causes the premature component of the QRS complex to become shorter and the QRS complex more normal, this is because of acceleration of normal AV conduction, which causes more of the ventricle to be activated in a normal manner. Occasionally, the premature component may disappear completely, this "pseudonormalization" can be distinguished from true normalization by the fact that the P-R interval remains short True normalization may occur also, in this case the P-R interval becomes longer. This can be explained by assuming either that

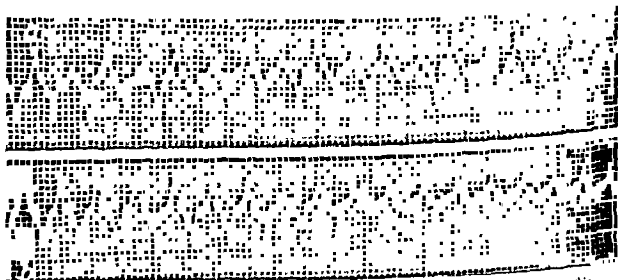

Fig. 11-42. Alternating preexcitation appearing in a cat after injection of myocardial sympathin. B The premature component of the QRS complex appears progressively later and disappears at the end of the tracing

at high heart rates conduction in an anatomic aberrant pathway does not take place because of fatigue, or that the mechanical effect of atrial contraction is smaller because of the decreased stroke volume On the other hand, decrease of heart rate, such as that caused by carotid sinus pressure, the late phase of the Valsalva maneuver (Fig 11-41), or medication with *Prostigmine*, *Mecholyl*, or *digitalis*, usually increases the duration and magnitude of the premature component of the QRS complex because of slowing of normal AV conduction During this effect, the P-R interval remains short but the P-J interval increases In many cases, the above factors led to the appearance of preexcitation complexes

The remarkable constancy of the P-R interval in preexcitation may be due to the fact that an aberrant pathway, consisting of nondifferentiated ventricular muscle, would not be influenced by the vagal effects which cause prolongation of the normal AV conduction together with bradycardia It would also be in keeping with an electrical, but not with a mechanical, excitation of a ventricular irritable focus by the atrium, as mentioned above The only factors which influence the P-R interval seem to be *quinidine* and *procaine amide*, which usually cause the premature component of the QRS complex to appear progressively later, to become smaller, and finally to disappear completely (Blinder et al , Zapata Dias et al) In these cases, the P-R interval becomes longer while the P-J interval is usually unchanged In some cases, normalization takes place abruptly The action of these drugs would be in keeping with a slowing of conduction in an accessory bundle, but not in the AV node, since they have a greater effect on nonspecific ventricular muscle It would also be in keeping with an ectopic ventricular focus stimulated by atrial activity, as the same drugs decrease ventricular excitability, a gradual and considerable prolongation of the P-R interval would be more difficult to explain on this basis, since the moment of excitation would then occur considerably after the maximal electrical and mechanical effects of atrial excitation The occurrence of delayed preexcitation would also be difficult to explain on this basis Finally, the occurrence in some cases of preexcitation of Wenckebach's periods, i e , of progressive prolongation of the P-R interval leading to complete AV block followed by shortening of the P-R interval (Levine and Burge, Scherf et al., 1953; Hecht et al., 1957), could not be explained on any other basis except that of an aberrant AV bundle.

When AV nodal beats occur in preexcitation, either spontaneously or during the initial, bradycardiac action of atropine, during carotid sinus pressure, or after injection of Neosynephrine (Ohnell), they always show a normal QRS complex if the P wave follows the QRS complex. In these cases, the ventricle is excited entirely through normal pathways before preexcitation can take place Occasionally, when the P wave precedes the QRS complex slightly, a delta wave may appear, but it is always shorter than in the usual preexcitation complexes In a few cases, this wave was present even when no P wave preceded the QRS complex; in these cases the rhythm could have originated in the accessory bundle, or this bundle could have originated in the AV node itself

Paroxysmal tachycardia was found in about 70 per cent of all cases showing the Wolff-Parkinson-White pattern, in children, this percentage was 93 per cent (Vacheron). On the other hand, it constitutes about 5 per cent of the cases of paroxysmal tachycardia, in children this percentage was 12 per cent (Nadas et al) The higher incidence in children can be explained by the fact that electrocardiograms in children are seldom taken unless there is a conspicuous alteration of rate or an arrhythmia In most cases the QRS complexes were regular and narrow, and were followed after about 0.10 sec by inverted or diphasic P waves, the premature portion of the QRS complex was absent. The tachycardia was therefore designated as nodal, but, in contrast to typical nodal tachycardia, the P waves were often upright in lead I The appearance of this type of tachycardia can be explained by means of a special form of "circus movement" from the ventricle to the atrium through an accessory AV bundle, and back to the ventricle through the normal AV conduction system. It could not be explained at all on the basis of an excitable ventricular center, for this would cause a ventricular tachycardia.

The beginning and end of the paroxysmal tachycardia was studied repeatedly only in a few cases. In two of them (Juncadella Ferrer,

Tommaselli), frequent atrial extrasystoles were present; if they appeared late, they were followed by QRS complexes with delta waves, but if they appeared early enough, they were followed by a narrow QRS complex, followed in turn by a diphasic P wave and an access of paroxysmal tachycardia. Still earlier extrasystoles were followed by narrow QRS complexes only, or were blocked. Apparently circus movement becomes possible only if an atrial extrasystole appears early enough to find the accessory bundle still refractory but late enough for it to recover by the time excitation is conducted to the ventricle The attack was terminated either by a diphasic P wave after progressive lengthening of the P-R interval (block in the AV node) or suddenly by a QRS complex (block in the accessory bundle). In other cases (Rosenbaum et al., 1945; Katz and Pick), the attacks were initiated in the same way by lower nodal extrasystoles, with the first few complexes of the tachycardia showing a wide QRS complex without a slow initial component, because of aberrant intraventricular conduction. In the case of Lyle, the atrial extrasystoles elicited runs of tachycardia with wide QRS complexes showing delta waves, in this case, the normal conducting system could have been still refractory while excitation was conducted down the accessory bundle, but became conducting by the time excitation reached it retrogradely from the ventricle These cases show that a premature stimulus is necessary to establish circus movement and explain the numerous observations in which no paroxysmal tachycardia appeared until the occurrence of some acute infection, which could have precipitated extrasystoles responsible for circus movement In most cases the tachycardia can be interrupted by digitalis, while in some, quinidine is more effective This can be explained by assuming that circus movement can be terminated either by blocking the AV node with digitalis or by blocking the accessory bundle with quinidine

In a minority of the cases with preexcitation, *atrial fibrillation* is registered during the accesses of paroxysmal tachycardia, and a few cases show *atrial flutter* (Pick and Katz). The case of Tommaselli shows clearly how the typical "nodal" type of tachycardia attributed to circus movement through the aberrant bundle can be transformed into atrial flutter and finally into atrial fibrillation; any rapid stimulation of the atria can lead to the same sequence. These arrhythmias can accordingly be explained on the basis of an accessory bundle, but not on that of an excitable ventricular center. When atrial fibrillation is present, runs of normal QRS complexes usually alternate with groups of complexes showing very wide delta waves (complete preexcitation). These groups can be explained by assuming that when excitation takes place over the accessory bundle, the normal AV bundle is excited later and retrogradely, and therefore recovers its conductivity later than the accessory bundle, so that the constantly circulating fibrillation waves are likely to enter the accessory bundle again (Pick and Katz). As in atrial fibrillation, coordinated atrial contractions are absent, the appearance of preexcitation in these cases cannot be explained by mechanical effects of atrial contraction, while stimulation by electrical effects would still be possible. One peculiarity of atrial fibrillation with preexcitation is that the ventricular rate is usually very rapid, and the usual slowing effect of digitalis medication on this rate is absent (Katz and Pick, Giraud et al.). This can be explained by the fact that this slowing effect is due to a blocking effect of digitalis on the AV node, the drug would not have effect on a muscular accessory pathway. *Quinidine*, which blocks also the accessory pathway, must be combined with digitalis in such cases.

In many cases of preexcitation, the paroxysmal tachycardia was interpreted as being of ventricular origin, but closer scrutiny of the tracings always made it seem probable that in reality *atrial fibrillation with complete preexcitation* was present (Langendorf et al; Giraud et al.) True ventricular tachycardia becomes probable only in cases where ventricular extrasystoles of the same form had appeared previously (Frau and Maggi). In these cases, the explanation of the syndrome as due to an excitable ventricular center is more likely.

Occasionally the slope of the premature component of the QRS complex in preexcitation complexes may be so slight that this component can be mistaken for an ascending P-R segment; if this slope is less than 2.5 mv/sec, the term "type B" was used by Öhnell, but we shall call this pattern *low-voltage preexcitation*. This type often results from superposition of a descending P-R segment

n the *delta wave* and usually becomes more pical with slowing of the heart rate, especially n the precordial leads. A much more common attern shows a short P-R interval but an apparently normal QRS complex. It can represent *preexcitation* with a very steep and rapid delta wave, but this diagnosis can be made with certainty only if QRS complexes of different configuration and with a longer P-R interval can be observed to appear. In this type of "rapid preexcitation," designated as "type C" by Ohnell, the accessory bundle could terminate in the bundle of His. On the other hand, the pattern can correspond to accelerated conduction in the AV node. Lown et al found that the incidence of *paroxysmal* tachycardia in such cases was much less than in typical preexcitation (only 10 per cent), while the percentage of cases among females was much greater (70 per cent), most of them had signs of adrenal cortical overactivity. In some of these cases, the P-R interval became longer after digitalis administration but the QRS complex remained identical, and in these an accessory bundle could be definitely excluded.

The recognition of preexcitation is important, first of all because, although deaths due to paroxysmal tachycardia have been reported in this condition, its prognosis is much better *than* that of left bundle branch block with *which it may* be confused. The differentiation is easy in the presence of a typical delta wave, but complete preexcitation may look almost exactly like bundle branch block, especially if the P-R interval *is borderline* or atrial fibrillation is present. Usually, the initial *slope of the* QRS complex in right precordial leads is steeper in *bundle branch* block than in preexcitation, but sometimes *a definite* diagnosis can be made only by conversion *to sinus rhythm or* by application of agents which cause acceleration of AV conduction or true normalization. A Valsalva maneuver *or* subcutaneous injection of 1 mg atropine may cause the appearance of nodal escape beats with a normal QRS complex, accelerated AV conduction, or pseudo normalization. Slow *intravenous* injection *of procaine amide* at the rate of 200 mg/min up to 1 Gm caused normalization in 7 out of 9 cases without side *effects* (Zapata Dias et al.)

Preexcitation *complexes* showing a *negative* delta wave in leads I or II *or* III *may* imitate the deep Q wave of myocardial *infarction. On* the other hand, *positive* delta waves may prevent the deep Q waves of *infarction from* appearing, and old *infarction* can be recognized *in such* cases only after normalization. The changes of the R wave and S-T segment caused by infarction can also be masked by preexcitation, but in most cases, *closer inspection allows their recognition*. The *secondary* changes of the T wave and S-T segment in [illegible]tation are always opposite in direction [illegible] ponent (Fig 11-40). The total QRS [illegible] (ventricular gradient) remains the same (Bercun et al.). Accordingly, if the S-T segment [illegible] in a lead where the premature [illegible] tive or only slightly positive, these changes [illegible] to be primary and to indicate additional myocardial *damage. It must* be emphasized, however, that the primary T-wave *inversion* may appear in preexcitation without myocardial infarction after accesses of paroxysmal *tachycardia*, especially if treated with quinidine, in these cases, the T-wave *changes* remain after normalization. Another source of error may appear in rudimentary preexcitation, where the change in the QRS area may not be sufficient to cause an abnormal configuration of the QRS complex *but sufficient* to cause depression of the S-T segment and a *diphasic T wave*, which can be erroneously interpreted as *denoting myocardial* damage.

In the presence of *paroxysmal tachycardia*, the recognition of preexcitation is important *for treatment, since* if circus movement through the *accessory* bundle is the cause of tachycardia, quinidine *or procaine* amide *should* be beneficial even if this appears to be *"supraventricular"* Quinidine will also *prevent* the appearance of single atrial extrasystoles, which are often *instrumental in precipitating an attack*. Recently *Chlorpromazine* has been found beneficial, alone or in conjunction with *procaine amide, even where* the latter alone was ineffectual (Giraud *et al.*). The presence *of upright P* waves in lead I *in "nodal tachycardia"* or of the peculiar groups of wide QRS complexes in atrial fibrillation makes preexcitation *probable*, but it can *be established* only when delta waves can be *identified in* previous tracings or *appear* between attacks. It must be *emphasized* that *after* the tachycardia has

been stopped with quinidine, preexcitation complexes may not appear as long as the quinidine effect persists; an electrocardiogram repeated several days after termination of treatment is therefore more likely to disclose preexcitation (Blinder et al.). The ultimate goal in the treatment of tachycardia due to preexcitation would be to remove surgically the accessory bundle or the point of intimate contact between atrial and ventricular muscle. Its precise localization can be made satisfactorily from the configuration of the delta wave.

11

Double rhythms (pararrhythmias)

CORNELIO PAPP

One of the basic laws of cardiac physiology is that "a pacemaker working at a faster rate suppresses any potential secondary or tertiary pacemaker having a lower rate." Since, under normal conditions, the SA node forms impulses at a faster rate than the AV node or the intraventricular centers, in normal conditions it remains in sole control of cardiac rhythm.

In *double rhythms,* two pacemakers are active simultaneously, one of which is usually the SA node. The secondary pacemaker, which *may be situated anywhere in the atria,* the node, the bundle, or its branches, may form impulses at a higher or lower rate than the SA node For the existence of a double rhythm, it is essential that the slower pacemaker be protected from the faster one Such a "protection block" has been shown to exist and prevents the *suppression of the rhythm* created by the SA node or the ectopic pacemaker, whichever is the slower of the two

Double rhythm may manifest itself in two different forms

1 *AV dissociation* Here the rhythm of the atria is directed by the SA node, that of the ventricles, by the AV node. The SA rhythm, usually slower, is protected by a unidirectional block which prevents the nodal impulse from spreading backwards to the SA node, while *there is no obstacle to the spreading of sinus impulses to the AV node* The conducted SA impulses produce a transient disturbance of the AV nodal rhythm (dissociation with interference)

2 *Parasystole* The SA node is in command of atria and ventricles An ectopic (usually ventricular) pacemaker working at a slower rate, is protected by a *block of entry* from the faster SA impulses. This block, too, is unidirectional and *allows the ectopic pacemaker to assert itself and to interfere with the basic rhythm.*

The main difference between these two double rhythms—apart from the dissociated activity of the two pairs of chambers in AV dissociation—consists in the way the two pacemakers interfere with each other. In AV dissociation, it is the SA node which disturbs the ectopic pacemaker, while *in parasystole, it is* the ectopic pacemaker which interferes with the SA rhythm.

ATRIOVENTRICULAR DISSOCIATION

When the rate at which impulses form in the AV node is superior to the rate at which it *receives impulses from the SA node, AV nodal rhythm results. This condition arises* when impulse formation is depressed in the SA node or exalted in the AV node, or when both these conditions exist. Since the physiologic property of the nodal tissue is that of unidirectional conduction, and impulses are *transmitted readily* from atrium to ventricle (but only with *difficulty in the reverse direction*), *retrograde block may arise and the SA* node will continue to beat independently *How* many of the SA impulses are *so timed as to* fall outside the refractory period and "capture" the ventricle depends upon the relative *rates of the two pacemakers and the duration of the refractory period of* both the junctional tissues and the *ventricles. If the AV* nodal rhythm is rapid, the refractory *period* shortens, and, with a slow SA rhythm, ventricular

been stopped with quinidine, preexcitation complexes may not appear as long as the quinidine effect persists; an electrocardiogram repeated several days after termination of treatment is therefore more likely to disclose preexcitation (Blinder et al.). The ultimate goal in the treatment of tachycardia due to preexcitation would be to remove surgically the accessory bundle or the point of intimate contact between atrial and ventricular muscle. Its *precise localization can be made satisfactorily* from the configuration of the delta wave.

Since in most of the published cases, the ventricular rate was faster than the atrial rate, this was thought to be an essential feature of AV dissociation Laubry and Lequime (1933) and Laubry and Puddu (1936) proved that this is not necessarily so and that certain factors (digitalis, toxic agents), which may produce SA depression and a passive escape of the node, may also exalt nodal activity They published cases with ventricular rates faster than or similar to the SA rates (*isorhythmic dissociation*).

The QRS complexes are commonly supraventricular. They may have a bizarre shape, because of aberrant intraventricular conduction caused by early appearance (Fig. 11-44B) of an infranodal pacemaker.

The QRS complexes conducted from the SA node may have a slightly different shape (Fig

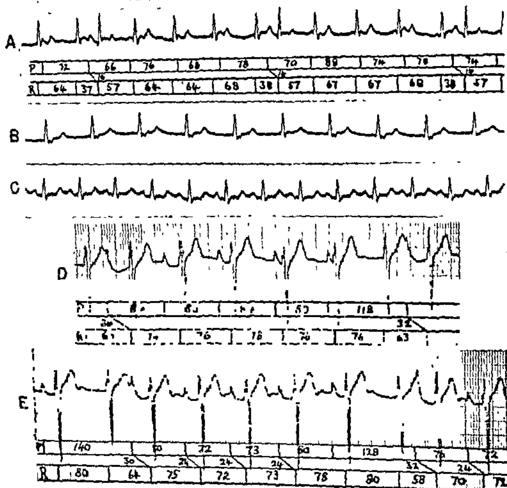

Fig. 11-43 Lead II A. *Mar. 27, 1957* AV dissociation with *interference*; third, eighth, and last beats, which are premature, are conducted. B. *Mar. 29* nodal rhythm with *retrograde* conduction. "captures" may not take place. But in the same case, slight variations of the rates may produce a shift in the responsive and refractory phases, and *interference beats* may appear. Thus, the distinction of AV dissociation with or without interference is purely artificial.

The term AV dissociation is often loosely applied to AV heart block. AV heart block is due to depression or interruption of conduction, while in *AV dissociation*, the SA impulse fails to reach the ventricle because of its arrival during the normal refractory phase following a previous impulse (Katz, 1946).

Experimental Findings. Rothberger and Winterberg (1910, 1912) have shown that the development of AV nodal rhythm in dogs is preceded by a short phase in which the atria are controlled by the SA node and the ventricles by the AV node In other experiments, occasional SA impulses interfered with the ectopic pacemaker Ganter and Zahn (1912) obtained similar results. Scherf (1929) produced AV dissociation during aconitine intoxication. Luten (1925), in studies on digitalis intoxication in dogs, found that AV dissociation with a ventricular rate higher than the atrial rate preceded ventricular tachycardia. Van Bogaert (1933) arrived at similar conclusions with ouabain

Clinical Findings. Wilson (1915) was the first to recognize AV dissociation with interference, and White (1916) described two further cases, to which another was added by Hewlett (1923). It was Mobitz (1923) who coined the term *interference dissociation,* which Scherf (1926) improved to *dissociation with interference* Mobitz also gave a correct interpretation of the first case ever published but not recognized (Wenckebach, 1906) Lewis (1925) and Wenckebach and Winterberg (1927) published extensive reviews, these were brought up to date by Scherf and Schott (1953), Holzmann (1955), and Katz and Pick (1956)

Most cases were described in the course of acute rheumatic carditis, in which the incidence is about 10 per cent (Oettinger, 1935). Diphtheria (Korth and Schrumpf, 1936) and other acute infections may also cause it. Digitalis overdosage as well as acute infections were considered in the cases of Bloom and Perlow (1930), Laubry and Lequime (1933), and Laubry and Puddu (1936). Scherf and Boyd (1948) believe that dissociation with interference is rare in nondigitalized patients, but only 2 of the 12 cases of Cutts had digitalis. Quinidine sensitivity may also cause it (Linenthal et al., 1953). These factors often act in combination; simultaneous administration of quinidine and digitalis, operative trauma, anesthesia and digitalis—each was responsible in single cases of the author's series. It has also been observed with coronary heart disease and syphilitic aortitis, and exceptionally during hypertensive crises of adrenal tumors (Hegglin and Holzmann, 1937). While, in most of these cases, AV dissociation was transient, in a child of Ledoux and Arcay (1936) with a normal heart, it had been persisting for years. Since persistent AV dissociation was observed in association with atrial septal defect, it may exist as a congenital variety (Papp, 1957).

The diagnosis is made through the electrocardiogram. The clinical impression is that of atrial extrasystoles, since the interfering beats are premature and are not followed by a compensatory pause. The irregularity also disappears on effort, for SA acceleration may temporarily abolish AV dissociation. The venous pulse may show *giant waves* when atrial and ventricular contractions coincide. Coexistent SA bradycardia may cause syncope.

Electrocardiographic Patterns. The varying SA rate (if SA arrhythmia is present), the coexistence of latent or partial heart block, the tachycardia caused by an irritable AV node, the variations of the refractory period of the junctional tissues and the ventricles, the transition into AV nodal rhythm may cause most intriguing tracings of complex arrhythmias

The *common pattern* of AV dissociation with
interference is shown in Fig. 11-43A. The average
atrial rate is 90 and, therefore, slower than the
average ventricular rate at 110, there is SA ar-
rhythmia, while the AV nodal rhythm, except
for the beat following the conducted sinus impulse,
is regular. The third to eighth and last ventricu-
lar complexes are transmitted to the ventricle with
a normal P-R interval and are premature. Only P
waves falling on top of the T wave (end of the
refractory phase) are conducted. The two rates
are so aligned that no P waves fall in late diastole
and can reach the ventricle. The three conducted
beats form the only link between the SA and AV
nodal rhythms.

As soon as the SA rhythm slows, dissociation with interference appears During maximal deceleration, SA bradycardia at an average rate of 39 develops; a bigeminal rhythm consisting of a nodal escape and a conducted beat keeps the ventricular rate at 80 (Fig 11-44B). When the vagal effect subsides, SA *rhythm* is again restored (*last two cycles* of Fig 11-44C). The P waves, which appear at a distance of 0 26 to 0 37 sec after the nodal escapes, are conducted to the ventricles at a speed of 0 31 to 0 34 sec (Figs 11-43D, E, and 11-44) This may suggest a reciprocal *rhythm*. However, if the P waves are magnified through use of a right atrial lead and double amplification, it becomes evident that all P waves are upright and of SA origin, and that there is no retrograde conduction (Fig 11-43D, E). Even so, the reactivation of the SA node after the nodal escape suggests that the latter is instrumental in this, either through a mechanical effect (White, 1921, Rosenbaum and Lepeschkin, 1955) or by improvement of the circulation in the SA node If this is so, the two pacemakers also work in relay, the AV node reactivating the SA node and this then taking over the lead for a few beats until a longer SA standstill occurs which provokes a nodal escape

AV dissociation due to irritability of the AV node is rare and forms a link with paroxysmal tachycardia (Fig 11-45)

Contrary to Figs 11-43D, E, and 11-44, which show SA bradycardia, the basic disturbance is an *ectopic* atrial tachycardia at an average rate of 128 with 2:1 AV block and a P-R interval of 0 24 *to* 0.28 *sec* (Fig. 11-45, bottom row). Slight slowing of the SA rhythm produces an AV nodal [illegible], which [illegible], during [illegible]wo rates soon equalize, slight slowing of the AV *rhythm* coincides with *slowing of the SA rhythm* (Fig. 11-45, top row), until a P wave falls late enough in diastole to capture the ventricles (sixth R wave). The dissociation, however, persists, even though the AV nodal rhythm has become slow; a P wave falling late in diastole remains blocked because of coexistent AV block. The same factors which produce an irritability of the SA node act on the AV node as well, which explains the alignment of the two rates during the tachycardic phase.

The association of 2:1 AV block with AV dissociation, but without nodal irritability, has a different electrocardiographic pattern. Conducted beats here have an aberrant pattern which appears when the SA rhythm slows. The ectopic center is emerging only when the half SA rate becomes less than the autonomic rate of the ectopic center. The number of impulses discharged by the SA node is of secondary

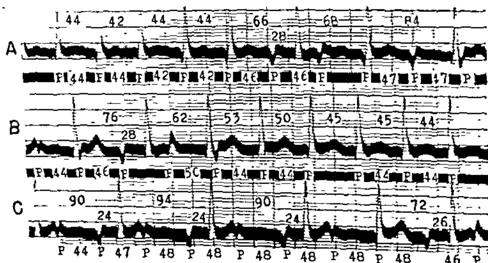

Fig 11-45 Lead II AV dissociation with "irritable" AV node. A. 11-43A) because of different spread of the SA impulse in the bundle. The P-R interval of the SA beats may be normal (Fig. 11-43A) or prolonged (Figs. 11-43, 11-44, 11-45). The prolongation may be due to latent heart block (long P-R interval), early conduction before complete recovery of the bundle takes place, or both. There is an inverse time relationship between the R-P period and the P-R interval of the conducted beat (Katz, 1946, Katz and Pick, 1956). The later the P wave appears in diastole, the faster is the AV conduction. In Fig 11-43E, the P waves appearing on top of, or shortly after, the preceding T wave are conducted to the ventricle at a speed of 0 30 or 0.32 sec, the P waves appearing later in diastole are conducted in 0 24 sec, which was the fastest conduction time of this patient, who had latent heart block. Latent heart block is frequently found in AV dissociation and is a predisposing factor, for impairment of forward conduction favors the development of retrograde block The distance between the conducted ventricular complex and the following AV nodal beat is usually the same as between two nodal beats, since nodal automatism is quickly restored (Figs 11-43D, E, and 11-44), but it may be shorter (Fig 11-43A) or longer.

The shortening has been explained by Scherf and Schott (1953) by the late appearance of the SA beat because of delayed conduction in the bundle (see slight aberrance in Fig 11-43A) while the nodal beat is on time. If the distance is slightly prolonged, it is due to fatigue of the conducting system; if the pause is longer and is equal to the distance between a conducted P wave and the next nodal R wave, following a conducted ventricular complex, one has to assume that *concealed conduction* (Langendorf, 1948) has taken place. This means that the sinus impulse reached the AV node, destroyed the immature AV impulse, and was blocked on its way to the ventricles, so that it did not become electrically visible. The same phenomenon was earlier described by Korth (1941) as *incomplete interference*, and explained by Schott (1937) as a sign of impaired conduction in the bundle.

AV dissociation may appear as a *passive ectopic rhythm* through SA bradycardia or SA block, it can then be temporarily abolished by exertion (Fig. 11-44A).

ectopic beats is a multiple of a *common* denominator *representing* the cycle length of the ectopic rhythm This can be easily calculated if two *extrasystoles are* seen in sequence; if they are separated from each other by longer stretches containing SA *beats, the refractory period* has to be determined on the basis of the shortest "coupling" separating the *extrasystole from* the previous *SA beat. The* latent beats have to fall within the refractory period, which may be much longer *than the* Q-T period, especially when the rate of both the SA and the ectopic pacemaker is slow An *example* is shown *in* Fig 11-46, where the SA rate is 43 and the ectopic rate is 34 The shortest "coupling" over long *stretches of records* was 0 76 sec (Fig. 11-46), all ectopic impulses following at a shorter distance after the previous SA *impulse remain* latent (interrupted vertical arrows). The parasystolic center shows more irregularity than *usually observed–the cycles* should not vary by more than 0 05 sec (Pick, 1953)–yet the varying "coupling" and the identical shape of *extrasystoles make* the diagnosis certain.

More than one parasystolic *center may* be active *simultaneously* (Holzmann, 1935); cases of atrial parasystole have also been described (Scherf and Schott, 1953). The parasystolic center may appear only *intermittently when both rates are* stable and so linked with each other that the ectopic impulses mostly fall during the refractory period. Carotid sinus *pressure* may suppress the SA rhythm, the parasystolic *rhythm remaining* in sole *control* (Mueller and Baron, 1953). *Amyl nitrite* in-

importance; it is the number of impulses reaching the bundle which determines the activity of the secondary pacemaker (Oettinger, 1935; Dressler et al., 1952).

Transition from AV dissociation to AV nodal rhythm is not uncommon (Fig. 11-43B); the two arrhythmias are interrelated, and the difference consists only in the presence or absence of retrograde block AV dissociation may also appear as a transient phase under quinidine treatment for atrial fibrillation before SA rhythm is established. It is often observed during acute rheumatic fever in combination with almost any arrhythmia (Bain, 1939; Vakil, 1954).

Prognosis and Treatment. *Prognosis* depends on the underlying cause. AV dissociation has little significance if it appears in a patient with otherwise healthy myocardium, but this is rarely the case. Its appearance during infections means cardiac injury, which may be slight or severe, its persistence after subsidence of rheumatic arthritis is a warning that carditis is still active Should it develop during treatment with digitalis or quinidine, the drugs should be stopped, for the disturbance is evidence of toxicity

Treatment has no place in AV dissociation. When the latter arises as a passive ectopic rhythm, it is an expression of a normal cardiac mechanism brought into play by depression of primary impulse formation Syncopal attacks due to SA bradycardia cease as soon as nodal automatism is established. If AV dissociation is due to nodal irritability, treatment should be that of paroxysmal tachycardia.

PARASYSTOLE

Parasystole, like AV dissociation, involves the concept of two simultaneously and independently acting pacemakers, one of which is in the SA node, the other usually in one of the ventricles. Such a possibility was first shown to exist by Fleming (1911) He imagined that the ectopic focus lies in "what may be called a backwater of primitive cardiac tissue" and that "physiological stimuli passing down the main channel are unable to disturb the point where ventricular stimuli arise", thus, the slower ventricular focus remains protected from the faster SA impulse. A *protective block* was assumed by Kaufmann and Rothberger (1919), who later (1922) made the first extensive study of the coexistence of two independent centers of impulse formation. In cases with ventricular rhythm faster than that of the SA pacemaker, it was thought that there might be an *exit block* which prevents the dominance of ectopic pacemaker and the transformation of parasystole into ventricular tachycardia. The term "block" applied in this sense is a misnomer, for the emphasis is not on inhibited conduction but on diminished excitability; excitability in relation to strength of the dominant rhythm determines the function of the ectopic center (Scherf and Chick, 1951).

Scherf (1927) was able to produce short periods of parasystole in dogs by mechanical and electrical stimuli after reduction of cardiac excitability with quinidine or sensitization of the heart with barium chloride and aconitine Longer-lasting parasystole, without mechanical stimulation, was produced by application of veratrine; parasystole so produced fulfilled most of the clinical criteria.

Parasystole is rare, its incidence being about 0 04 per cent of all routine ECGs recorded in a general hospital (Scherf and Boyd, 1950). It is mainly observed in coronary heart disease and is believed to be always evidence of an abnormal heart, except for the exceptional cases of nodal parasystole (Pick, 1953). Whether this belief can be upheld is questionable, since cases with normal hearts have been described (Singer and Winterberg, 1920, Heinz and Eldridge, 1957). Scherf and Schott (1953) found 11 cases without structural heart disease among 49. Most of the patients with organic heart disease were experiencing heart failure and were receiving digitalis, stopping the drug abolished the ectopic rhythm (Holzmann, 1935).

Electrocardiographic Patterns. The common electrocardiographic pattern is that of ventricular extrasystoles of identical shape. These appear at a varying distance from the SA beat and, therefore, are not induced by it, the "coupling" is variable, as opposed to the usual form of extrasystole to be observed in bigeminal rhythm. In fact the term "coupling" should not be applied, since the ectopic beats appear as cycles of an automatic rhythm, the emergence of which is regulated by the refractory phase of the dominant rhythm. When SA and ectopic impulses fall together, fusion beats result, having an intermediate shape between ectopic and SA beats. The final proof of parasystole can be given if the distance between two

ectopic beats is a multiple of a common denominator representing the cycle length of the ectopic rhythm This can be easily calculated if two extrasystoles are seen in sequence, if they are separated from each other by longer stretches containing SA beats, the refractory period has to be determined on the basis of the shortest "coupling" separating the extrasystole from the previous SA beat The latent beats have to fall within the refractory period, which may be much longer than the Q-T period, especially when the rate of both the SA and the ectopic pacemaker is slow An example is shown in Fig 11-46, where the SA rate is 43 and the ectopic rate is 34 The shortest "*coupling*" over long stretches of records was 0 76 sec (Fig. 11-46); all *ectopic impulses* following at a shorter distance after the previous SA impulse remain latent (interrupted vertical arrows). The parasystolic center shows more irregularity than usually observed—the cycles should not vary by more than *0.05 sec* (*Pick*, 1953)—yet the varying "coupling" and the *identical shape* of extrasystoles make the diagnosis certain.

More than one parasystolic center may be active simultaneously (*Holzmann*, 1935); cases of atrial parasystole have also been described (Scherf and Schott, 1953). The parasystolic center may appear only *intermittently* when both rates are stable and so linked with each *other that the ectopic* impulses mostly fall during the refractory period. *Carotid sinus pressure* may suppress the SA rhythm, the parasystolic rhythm *remaining* in sole control (Mueller and Baron, 1953). *Amyl nitrite* in-

halation may have an opposite effect through acceleration of the SA rhythm or improved blood supply (Holzmann, 1935).

Parasystole with exit block is said to exist when only some of the ectopic beats falling outside the refractory period become manifest. This usually happens in the rare cases where the rate of the ectopic centers is faster than that of the SA rhythm.

Though parasystolic rhythm should be strictly separated from bigeminal rhythm with fixed coupling, intermediate cases have been described. Holzmann believes that the same metabolic state of the cardiac muscle induced by digitalis can cause reentry and parasystole; constant coupling can be simulated by stability of the two rhythms. In the case of Mueller and Baron, coupled rhythm alternated with parasystole, and the authors believed that the ectopic impulses were not strong enough to emerge except during the supernormal phase of recovery. The reverse, i.e., the production of induced extrasystoles by the ectopic pacemaker, has also been described (Scherf and Schott, 1951) and explained by "*directional*" *block* around the ectopic center.

Parasystole is an electrocardiographic curiosity and not a clinical state, since it has no hemodynamic importance. Prognosis and treatment depend on the causative factors.

12

Cardiac resuscitation by external electric stimulation and countershock

PAUL M. ZOLL

Cardiac arrest presents a critical problem in many different clinical situations. It is a desperate emergency that requires prompt, energetic, and effective measures to effect resuscitation within the urgent time limit of about 4 min

Therapeutic procedures in the past have included cardiac puncture, intracardiac injection of drugs, and thoracotomy with cardiac massage, but the results with all these procedures are unsatisfactory in that the complete recovery rate is usually about 30 per cent (Stephenson et al , Cole)

A complicating factor in the emergency treatment of cardiac arrest is that the mechanism of the arrest may be either ventricular standstill or ventricular fibrillation. These mechanisms cannot be differentiated by the usual clinical means but only by an electrocardiogram or by direct inspection of the exposed heart, they tend to occur in somewhat different situations, however, and, most important, they require different treatment

Ventricular standstill occurs particularly in four clinical situations. (1) in the Stokes-Adams attacks which occur in patients with AV heart block; (2) during reflex vagal stimulation, as in patients with a hypersensitive carotid sinus, (3) during treatment with cardioactive drugs, such as digitalis, quinidine, and procaine amide, and (4) unexpectedly, during various diagnostic and therapeutic procedures, particularly in the operating room under anesthesia *Ventricular fibrillation* may occur in a Stokes-Adams attack, but it occurs most often as a disastrous complication of acute myocardial infarction.

The first problem to be considered in this chapter is ventricular standstill. Recently, the author has developed a new therapeutic approach to the problems posed by it. It is an externally applied cardiac pacemaker that produces effective ventricular beats, terminates ventricular standstill, and maintains an externally controlled rhythm for as long as necessary until spontaneous ventricular beats return. The electric stimulator functions like a natural intracardiac pacemaker but is under complete external control (Zoll, 1952). Figure 11-47 shows the electrocardiogram of a period of cardiac arrest terminated by electric stimuli and ventricular beats. The instrument[1] is easily applied and clinically practicable Two dials permit variation of rate of stimulation, and of amplitude of stimulation from 0 to 150 volts. Output wires carry the electric stimuli to the electrodes, which are smeared with conductive jelly and held on the precordium (usually in the V_2 and V_5 positions) by plastic handles or a rubber strap. The electric shocks go through the chest wall and produce ventricular beats This technique of external electric stimulation of the heart has now been used successfully by the author and others to resuscitate over 200 patients with Stokes-Adams attacks, 3 with reflex vagal stimulation, 4 with standstill due

[1] Manufactured by the Electrodyne Company, Norwood, Mass.

to drugs, and 8 with unexpected standstill, usually occurring during surgery (Zoll, et al., 1956a).

The first condition to be considered, Stokes-Adams attacks, occurs in patients with AV block and consists of attacks of cerebral ischemia due to very slow idioventricular rates, ventricular standstill, ventricular tachycardia, or ventricular fibrillation (Parkinson et al., 1941). The attacks are manifested by dizziness, syncope, prolonged unconsciousness, and convulsions, and they may end in death. The cardiac origin of such seizures becomes clear when cardiac arrest is observed during an attack, by the absence of a pulse or heart sounds. A more exact diagnosis is usually

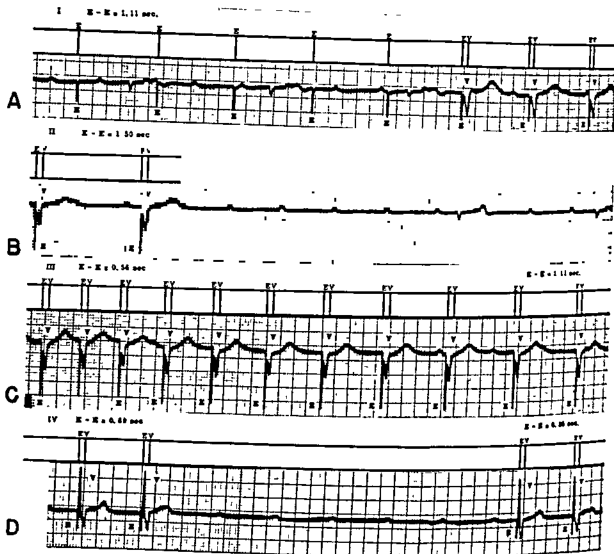

Fig 11-47. External electric stimulation in a patient with Stokes-Adams attacks. Lead aVF; standardization half-normal (1 mv equals 5 mm) A Interruption of idioventricular rhythm by faster externally paced beats The intensity of the electric stimuli, *E*, was progressively increased until ventricular responses, *V*, were produced. Three spontaneous idioventricular complexes (cycle length, 2 04 sec) occurred during ineffective stimulation; during effective stimulation at a faster rate (cycle length, 1 11 sec) they were suppressed. B. Resumption of idioventricular rhythm following external stimulation. When stimulation was stopped, the spontaneous ventricular pacemaker reappeared after a pause of 4.64 sec and regained its previous rate within three beats. C. Effective stimulation at varying rates. Each stimulus, *E*, produced a ventricular response, *V*. Each electrocardiographic ventricular response depended upon an electric stimulus, as shown by the constant relationship at widely varying rates of stimulation. D. Ventricular standstill during temporary interruption of stimulation. During a test period of 5.5 sec no stimuli were applied. No spontaneous ventricular contractions occurred during this interval, and the patient lost consciousness. Resumption of stimuli immediately gave ventricular responses, and the patient revived at once. (*Reprinted by permission of Grune & Stratton, from Circulation, 1954.*)

made by the observation of a very slow heart rate due to an idioventricular rhythm between attacks, however, *it is important to remember that evidence of any degree of AV block between attacks establishes the diagnosis and that, at times, in a patient with this disease, the pulse rate may be normal and AV conduction may be normal,* with a P-R interval of less than 0 20 sec

There are three major problems in the treatment of *Stokes-Adams attacks: (1) emergency resuscitation from a major attack,* (2) termination of persistent ventricular standstill, and (3) prevention of frequently recurrent attacks.

For a major attack with persistent syncope, emergency resuscitation must be effected promptly and the circulation to the heart and *brain must be restored within 3 or 4 min* Electrocardiographic identification of the mechanism of the attack is useful but, even when an electrocardiogram is not available, *treatment must be immediately instituted*

If the mechanism of the attack is ventricular standstill or is unknown, *the precordium should be struck forcefully* Then *cardiac puncture* should be *performed, the* tip of the needle should be embedded in the heart wall, and *the hub* of the needle should be tapped sideways *repeatedly to* stimulate ventricular beats If arrest persists, *epinephrine hydrochloride* may be injected through the needle into a *cardiac chamber,* care being taken not to put any within the myocardium

These measures should be tried in sequence *if there is delay* in applying the electric pacemaker They are *simple* and usually immediately feasible, but are frequently *ineffective* and *sometimes* produce fatal complications The *electric pacemaker,* on the contrary, is completely safe and is uniformly effective in terminating attacks due to slow idioventricular rates or ventricular *standstill* As soon as possible, therefore, the electric pacemaker should be *attached* to the patient and stimuli *of increasing* intensity *applied* until cardiac responses occur (Fig 11-47) If adequate intrinsic ventricular activity appears *following* resuscitation, *stimulation* may then be stopped However, if there is excessive delay in applying the cardiac pacemaker, *or if* the mechanism is ventricular fibrillation, these *measures* will fail

The *author* has now resuscitated *over 200* patients from Stokes-Adams attacks with the electric pacemaker In an early series of 50 cases, attacks due to *very slow idioventricular* rates were observed in 12 patients, and to *ventricular standstill* in 45 patients; *these* episodes of *cerebral ischemia* were all *terminated* immediately by electric stimulation. This dramatic effect was observed countless times Stokes-Adams attacks due to *ventricular tachycardia or fibrillation* were seen in 20 patients. It is clear that such *seizures* cannot be terminated by stimulation. However, in 8 patients with frequent attacks due to multifocal ventricular tachycardia *or fibrillation, continued external stimulation prevented* their recurrence.

If adequate intrinsic ventricular activity fails to appear *after successful* resuscitation, a new, second *problem is posed. It has heretofore* been impossible to observe ventricular standstill for more than the few minutes that life *would persist. For the first* time, we have in the *electric pacemaker a means* of producing heart beats under such *circumstances and* of maintaining life indefinitely (as long as 109 hr in *the* author's experience). With the patient kept alive by the external pacemaker, there is no *desperate emergency,* and heroic and dangerous measures are unnecessary. With careful, deliberate *infusions of diluted solutions of sympathomimetic amines,* particularly *epinephrine hydrochloride,* the author was often successful in arousing an idioventricular *rhythm,* in accelerating it to an adequate rate, i.e, *between* 30 and 45 per minute, and in maintaining it there *He also used norepinephrine* to maintain an adequate blood pressure *whenever necessary*

The *prevention of recurring attacks* is a third major problem of Stokes-Adams disease that is still largely unsolved. When the idioventricular *rate is too slow* (below *30 per minute*), *ephedrine sulfate* and *isoproterenol (Isuprel)* are often *useful* for long-term *maintenance* of heart rates *between* 30 and 45 *beats per minute.* When recurring attacks are due to *varying AV conduction, atropine, ephedrine,* and *isoproterenol* should be tried When the attacks are due to recurrent ventricular tachycardia *or* fibrillation, *ephedrine* and *isoproterenol again,* or the cardiac pacemaker, *may* be useful in *reducing* ectopic activity *by increasing* the basic ventricular rate;

quinidine and *procaine amide* are contraindicated in these patients with heart block and Stokes-Adams disease.

It is for this reason that a clear distinction should be made between patients with AV block who have Stokes-Adams attacks and patients without AV block who may have disturbances of ventricular rhythm. Episodes of ventricular arrhythmias that cause cerebral ischemia in the latter patients should not be called Stokes-Adams attacks but rather *cardiac syncope*, a much more general term. In them, there is no contraindication to quinidine and procaine amide.

Despite all the author's efforts and this new approach, many of the patients have died of Stokes-Adams attacks. These fatalities occurred because the electric pacemaker was not applied during a fatal attack when the episode occurred unexpectedly; because the attack was due to ventricular tachycardia or fibrillation and was not terminated by the electric pacemaker; or because of irreversible cerebral damage due to delay in applying electric stimulation. Several patients died of complications of their Stokes-Adams disease or of other primary disease, such as acute myocardial infarction, acute bacterial endocarditis, cardiac tamponade from multiple cardiac punctures, and congestive heart failure

Episodes of cerebral ischemia due to *ventricular standstill or fibrillation also occur in* patients without Stokes-Adams disease Certain of these episodes, as in the carotid sinus syndrome, are usually transitory, and are clearly due to reflex vagal stimulation The distinction between Stokes-Adams attacks and reflex vagal standstill is of clinical importance because of differences in the course, prognosis, and treatment of each condition. Again, this distinction is usually simple but ultimately depends upon the presence or absence of AV block at any time between attacks

External electric stimulation was repeatedly effective in resuscitating three patients with ventricular standstill due to reflex vagal stimulation. In all of them, episodes of ventricular arrest repeatedly interrupted normal sinus rhythm abruptly, producing syncope and convulsions. The precipitation of such episodes by carotid sinus pressure and their disappearance following the administration of *atropine sulfate* established their reflex vagal origin. More than 100 times, in these patients, external electric stimulation terminated ventricular standstill and restored an effective circulation

A third type of cardiac arrest occurs as a result of *depression of cardiac automatism* due to drugs. The author has observed three patients with attacks of syncope due to digitalis. With digitalis toxicity, SA block occurred, whereupon cardiac activity was maintained by nodal or ventricular pacemakers, intermittent failure of these pacemakers resulted in periods of ventricular standstill lasting as long as 1 min. External electric stimulation resuscitated the patients several times. With recession of the digitalis effect, the seizures stopped.

Two patients with ventricular standstill following intravenous administration of procaine amide in the treatment of ventricular extrasystoles and tachycardia, have also been resuscitated promptly by other workers by means of the external electric pacemaker.

Cardiac arrest may also occur in a fourth group of patients. Young, healthy, individuals without heart disease may develop cardiac arrest unexpectedly, while undergoing various diagnostic and therapeutic procedures, particularly while *under anesthesia* in the operating room. Though infrequent, each such accident is a dreadful catastrophe.

The commonly recognized mechanisms of unexpected arrest are ventricular standstill or *fibrillation, standstill is the* usual cause, occurring probably about 90 per cent of the time, and reflex vagal stimulation appears to be a frequent precipitating factor.

Electric stimulation of the heart has been effective in 11 such cases of unexpected cardiac arrest Three of these patients were observed by the author personally. The others were described to him in personal communications by the physicians concerned The cases occurred during various procedures, 10 during surgery, 1 during pericardiocentesis The cardiac arrest was terminated in each case by the electric pacemaker, so that thoracotomy and cardiac massage were not necessary. Eight of the 11 patients recovered completely; 2 died of unsuccessful cardiac surgery, and 1 died 5 hr after an abdominal operation

The author's experiences with the cardiac pacemaker indicate that external electric stimulation can resuscitate the heart from arrest that occurs unexpectedly under anesthesia during

surgery or other procedures, just as it does from the other types of cardiac arrest The technique has been applied safely in the operating room within the few minutes available for complete resuscitation. It seems to us, therefore, that external electric stimulation of the heart should be tried quickly, *even in the operating room*, before resorting to thoracotomy and cardiac massage.

In addition to these successful experiences, the author has personally attempted resuscitation with the cardiac pacemaker unsuccessfully in several patients who developed unexpected cardiac arrest, most, but not all, of them during anesthesia A brief list of the procedures involved indicates their wide variety and frequently insignificant nature They include jugular puncture, intravenous pyelography, bronchography, cardiac catheterization, endotracheal intubation, hip nailing, cholecystectomy, and thoracic and cardiac surgery In a few, the circulatory arrest was due to ventricular fibrillation, and stimulation was ineffective In all the others, electric stimulation was applied too late, over 5 min after onset of arrest, and usually after prolonged, ineffective massage

These failures emphasize two critical problems of unexpected cardiac arrest First, the responsiveness of the heart to stimulation diminishes progressively with continued anoxia Second, effective ventricular beats *cannot* be stimulated by the pacemaker during ventricular fibrillation The time interval between arrest and the resumption of effective ventricular output must be brief, probably less than 3 or 4 min, if cerebral and cardiac function is to return unimpaired Avoidance of excessive delay depends upon immediate recognition of the cardiac arrest and then the immediate application of external stimulation and institution of a *prearranged* program for resuscitation

Immediate recognition of arrest at its onset depends upon continuous monitoring of cardiac activity The author has developed a practical *monitoring device*[2] combined with the pacemaker, and has used it to great advantage in the operating room and in patients with recurring Stokes-Adams attacks, to signal immediately the cessation of heart beats.

[2] Manufactured by the Electrodyne Company, Norwood, Mass.

Briefly, the monitor amplifies the electric activity of the heart like an electrocardiogram, so that patient contact and pickup of impulse are not difficult, it gives *an audible as well as a visual signal of each beat*, so that undivided attention to the monitor is not needed, and *it rings a compelling alarm* with the onset of arrest. Furthermore, it shows the mechanism of the arrest promptly, so that there is no problem in *differentiating ventricular standstill from fibrillation* If standstill is seen, stimulation with the pacemaking half of the machine can be effected without delay through the same electrodes on the chest. Ideally, perhaps, such a monitor-pacemaker should be applied routinely to all patients under anesthesia Certainly the monitor-pacemaker should be applied beforehand to all patients undergoing anesthesia who present a particularly high risk of cardiac arrest. This specially vulnerable group includes patients with extreme debility, severe heart disease of any kind, AV block of any degree, patients receiving large doses of quinidine or procaine amide, patients with high serum potassium, patients with a sensitive carotid sinus, patients undergoing surgery involving the extraocular muscles, and particularly patients who have had previous episodes of cardiac arrest.

Immediately upon recognition of arrest, a rehearsed program of treatment should be instituted. The heart *should be stimulated* mechanically by striking the precordium forcefully, by cardiac needle puncture, or by cardiac manipulation through the diaphragm, if the abdomen is open These measures are simple and immediately feasible and are worth the few seconds necessary because they are occasionally *effective*. If no time has been lost in the recognition of arrest, it is proper to spend no more than 1 min in attaching and trying the cardiac pacemaker. This trial, which should be successful in most cases of ventricular standstill, can be made easily within this time limit if the electric pacemaker is close at hand and if the operating room personnel have been trained in its use by previous emergency drills

If the initial mechanism of cardiac arrest is ventricular fibrillation or if the patient is not resuscitated by external mechanical or electric stimulation, the chest must be opened promptly and cardiac massage begun. At the

same time the anesthetist must provide adequate respiratory exchange of oxygen. Once blood is being squeezed out of the heart by the surgeon's hand, the desperate urgency of the 3-min time limit is over and further measures can be undertaken, if necessary, with more care and deliberation.

If the ventricular fibrillation appears or persists in spite of effective massage, *defibrillation* should be attempted only after the myocardium becomes pink and firm, *countershock* with a 60-cycle alternating current of 120 to 150 volts for 0.15 sec applied across large electrodes on the heart is most effective for this purpose.

Ventricular standstill may persist despite effective massage or may recur following defibrillation. *Epinephrine hydrochloride* (1 ml of a 1:10,000 dilution) may be injected into the left atrial chamber and may be repeated in 3 min if necessary. If standstill continues and the myocardium is flabby, 5 ml of 10 per cent *calcium chloride* may be given. For persistent standstill, the electric pacemaker may be applied directly to the heart with a special bipolar electrode, so that massage need not be continued too long.

If resuscitation is successful, the patient should be kept under constant observation for 2 or 3 days, because arrest frequently recurs. The cardiac monitor-pacemaker is most useful in providing continuous information about cardiac activity during this time and in providing immediately available, effective resuscitation from standstill. In the last year we have saved two patients from recurrent arrest in this way.

The second mechanism by which cardiac arrest may occur is *ventricular fibrillation*. Countershocks of 60-cycle alternating current of 50 to 150 volts and for 0.1 to 0.2 sec applied across the exposed heart have been used for some time as an adjunct to cardiac massage to stop ventricular fibrillation. Recently the author and others have used similar countershock current of higher voltage experimentally to stop ventricular fibrillation by applying it *externally* across the unopened chest (Guyton et al.). The author has applied such high-voltage countershocks repeatedly in the experimental animal without producing damage to the heart, nervous system, or skin.

Furthermore, he found that externally applied countershock would also terminate atrial fibrillation, atrial tachycardia, nodal tachycardia, and ventricular tachycardia as well as ventricular fibrillation. The efficacy of the external countershock was clearly established by the repeated observation of the instantaneous cessation of these arrhythmias upon application of the electric current (Zoll, 1956c).

After these successful experimental observations, this technique was applied to ventricular fibrillation in man (Zoll, 1956b). The author has now stopped ventricular fibrillation twenty times in 11 patients. However, all but 1 of these patients died. In each fatal instance the countershock was applied after considerable delay (5 min or more), and effective beats did not return after defibrillation. It was recognized beforehand in most of these cases that the procedure had little chance of saving the patient because of the long delay. The underlying causes of fibrillation in these cases were acute myocardial infarction, digitalis intoxication, and Stokes-Adams attacks.

One patient survived. He had active Stokes-Adams attacks and was resuscitated from many episodes of ventricular standstill by the electric pacemaker, and from three episodes of ventricular fibrillation by external countershocks of 270 to 360 volts. In each instance the countershock was applied within 3 or 4 min after the onset of the fibrillation. Ventricular standstill occurred after each defibrillation, but external electric stimulation then evoked effective ventricular beats, which were followed shortly by an intrinsic ventricular rhythm and complete recovery. Figure 11-45 shows the electrocardiograms taken during one of these episodes. In the last year, the author has successfully resuscitated 8 patients over 400 times from ventricular tachycardia or fibrillation by external electric countershock.

The termination of atrial fibrillation, supraventricular tachycardia, and ventricular tachycardia by external countershock, in addition to the possibility of external defibrillation, has wide clinical potentialities that have not been completely explored. This technique may prove useful in desperate cases resistant to drug therapy, by providing a means of immediate termination of the arrhythmia without the dangers of prolongation of the arrhythmia and in those connected with massive drug administration.

The demonstrated efficacy of external coun-ershock in stopping ventricular fibrillation in ian provides a readily available and safe tech-ique for stopping this usually fatal arrhythmia. utside the operating room and in seriously l patients in whom thoracotomy and cardiac iassage may be particularly inadvisable, ex-ernal countershock may offer the only ef-ective therapy. In the operating room, con-inuous cardiac monitoring, immediate external lectric stimulation, and external electric de-ibrillation make up a combined technique oy which unexpected cardiac arrest may be ecognized promptly, and the patient may be esuscitated from ventricular standstill or fi-orillation, before resorting to the more for-midable and traumatic procedure of cardiac massage

The major difficulty with external electric cardiac stimulation is that the electric shocks which stimulate ventricular responses are often very painful. Although this pain is not impor-tant in the emergency resuscitation of an un-conscious patient from cardiac arrest, it is often very distressing when patients require prolonged or repeated stimulation for repeti-tive seizures, persistent absence of intrinsic ventricular beats, excessively slow idioven-tricular rates, or prevention of recurring ven-tricular tachycardia or fibrillation. These prob-lems arise most in patients with Stokes-Adams disease, whether it occurs naturally from car-diac disease or whether it follows cardiac sur-gery, particularly the repair of interventricular septal defects.

Several approaches to this problem of pain with stimulation have been developed. In the first place, analgesic agents like meperidine (Demerol) often make the pain more tolerable. Furthermore, careful application of the elec-trodes to the chest wall with moderate rub-bing of the skin may lower the threshold for

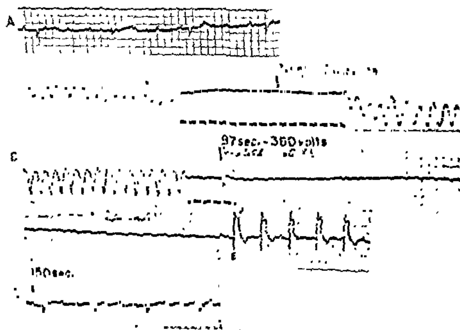

Fig 11-48 Resuscitation from ventricular fibrillation in a patient with Stokes-Adams attacks. Lead aVF, amplification half-normal (1 mv = 5 mm). A. Patient's usual idioventricular rhythm before seizure B Ventricular fibrillation that persisted after application of countershock of 300 volts The indicated times are from the beginning of the continuous electrocardiogram, 1 min after the episode began The broken line indicates when the electric activity of the heart was not being recorded ("instomatic" switch turned on) C. The two strips are continuous External countershock of 360 volts at 87 sec terminated the arrhythmia and produced ventricular stand-still External electric stimuli, E, at 60 volts produced ventricular beats, V, 12 sec later. D. Re-sumption of usual idioventricular rhythm within a few seconds after termination of electric stimulation. The patient regained consciousness promptly and recovered completely. (From Zoll, New England J. Med 1956)

stimulation with consequent reduction in the amount of pain.

A second approach has proved most useful in the management of atrioventricular block and cardiac arrest that follow cardiac surgery and constitute a major complication of open-heart surgery. *A modification of the technique* of external electric stimulation of the heart was introduced (Weirich et al., 1958), by *stimulating the heart directly* with an electric pacemaker. At the time of surgery, a wire is inserted into the myocardium and brought through the skin, where it is attached to an electric stimulator, and a second wire from the pacemaker is placed subcutaneously to complete the electric circuit. Effective cardiac stimulation is possible by way of the myocardial electrode at voltages (usually well below 10 volts) that do not produce any pain or skeletal muscular movement. This type of direct cardiac stimulation can be used freely and most effectively in the management of postoperative heart block for several weeks after surgery; in most instances, during this time, normal sinus rhythm returns and the difficulty is completely solved. In addition to the requirement of open thoracotomy to place the electrode, this technique does have two limitations. Infection may occasionally occur at *the site of exit of the wires through the skin.* Secondly, stimulation via the myocardial electrode becomes ineffective, usually within 8 weeks or less, apparently because of inflammatory reaction about the myocardial electrode. These difficulties make this method unsuitable for the long-term management of patients with Stokes-Adams disease.

Two interesting modifications of Lillehei's direct myocardial stimulation have been introduced to obviate the necessity for thoracotomy. One has been the introduction of a myocardial electrode by Thevenet et al. (1958) through a blind percutaneous puncture. This technique carries with it the risk and uncertainty of a blind puncture of the heart plus the original *limitations of cutaneous infection* and ultimate ineffectiveness of stimulation within a month or two.

The second modification, by Furman and Schwedel, is the introduction of an *intracavitary wire electrode* by way of a cardiac catheter passed up a vein of the forearm into the right ventricle. Direct cardiac stimulation at voltages less than 10 volts without pain was carried out by him in one patient with Stokes-Adams disease for over 3 months. Local skin infection is a problem with this technique also, but effective stimulation is apparently possible for longer periods than with the myocardial electrode. The additional possible complications of thromboembolism and trauma to the right-sided endocardium or valves were not encountered; anticoagulant therapy was maintained throughout the entire period of stimulation. This procedure is clearly most useful in patients with Stokes-Adams disease with persistent seizures, who cannot tolerate external electric stimulation. Under these circum*stances, the risks of the* procedure are clearly acceptable. It is equally clear, however, that this technique cannot be used indefinitely for the permanent maintenance of patients with Stokes-Adams disease throughout their lifetime. Better techniques of management, by pharmacologic agents or by electronic pacemakers that may be buried in the body and operate effectively and indefinitely, are under investigation for this ultimate goal.

13

Clinical differentiation of cardiac arrhythmias

RUSTOM JAL VAKIL

Nomenclature. The term *normal sinus rhythm* implies a regular rhythm of from 60 to 100 beats per minute, initiated at the SA node. Any deviation from normal has been referred to as *cardiac arrhythmia*, irrespective of whether the abnormal rhythm was regular or irregular. Such a procedure of labeling a perfectly regular rhythm, such as that of complete heart block, paroxysmal tachycardia, sinus bradycardia, or atrial flutter, as "cardiac arrhythmia" is definitely unscientific. Hence, arises the need for more scientific designations, such as abnormal heart rhythms, abnormal cardiac mechanisms, disorders of the heart rhythm, or dysrhythmias.[1]

Importance of Abnormal Heart Rhythms. Abnormal heart rhythms are of clinical importance for several reasons: (1) their incidence is high in clinical practice, (2) they are a source of anxiety to both patient and doctor, (3) they often focus attention on the correct diagnosis of the disease, (4) their diagnosis is often an essential prerequisite to successful treatment, (5) they may predispose to complications or untoward events, (6) they may alter the prognosis or outlook of an existing cardiac condition, and (7) their prompt treatment may postpone or avoid the occurrence of cardiac failure.

[1] In order to avoid this confusing terminology, Luisada (1948) suggested dividing these disturbances into (*a*) tachycardias, (*b*) bradycardias, and (*c*) arrhythmias. The complex of these disturbances he called "disturbances of the heart rate and rhythm."

Anatomicophysiologic Considerations. From early embryonic life until death, the conducting system of the heart has the power of automatic and rhythmic contraction. The conducting system is a specialized neuromuscular tissue, endowed with the power of initiating and conducting cardiac impulses.

The heart beat is normally initiated by the SA node, which, in normal conditions, has an inherent rate of stimulus formation greater than that of any other component of the conduction system. It is, therefore, referred to as the pacemaker of the heart; in the event of its being depressed or diseased, a subsidiary or secondary pacemaker takes over the function of initiating beats (nodal or idioventricular pacemaker).

CLASSIFICATION

Many different classifications of cardiac arrhythmias have been proposed from time to time, with alleged advantages, and later abandoned in favor of new ones. On the basis of the mechanisms involved, abnormal cardiac rhythms were classified into two major groups, viz., (1) *disturbances of impulse formation* (inclusive of various types of sinus or normotopic and ectopic or heterotopic rhythms), and (2) *disturbances of impulse conduction* (inclusive of sinoatrial, atrioventricular, and intraventricular blocks) by Vakil and Golwalla (1952).

The following classification of abnormal cardiac mechanisms or rhythms, recently proposed by the American Heart Association and based

stimulation with consequent reduction in the amount of pain.

A second approach has proved most useful in the management of atrioventricular block and cardiac arrest that follow cardiac surgery and constitute a major complication of open-heart surgery. A modification of the technique of external electric stimulation of the heart was introduced (Weirich et al., 1958), by *stimulating the heart directly* with an electric pacemaker. At the time of surgery, a wire is inserted into the myocardium and brought through the skin, where it is attached to an electric stimulator, and a second wire from the pacemaker is placed subcutaneously to complete the electric circuit. Effective cardiac stimulation is possible by way of the myocardial electrode at voltages (usually well below 10 volts) that do not produce any pain or skeletal muscular movement. This type of direct cardiac stimulation can be used freely and most effectively in the management of postoperative heart block for several weeks after surgery, in most instances, during this time, normal sinus rhythm returns and the difficulty is completely solved. In addition to the requirement of open thoracotomy to place the electrode, this technique does have two limitations Infection may occasionally occur at the site of exit of the wires through the skin. Secondly, stimulation via the myocardial electrode becomes ineffective, usually within 8 weeks or less, apparently because of inflammatory reaction about the myocardial electrode. These difficulties make this method unsuitable for the long-term management of patients with Stokes-Adams disease

Two interesting modifications of Lillehei's direct myocardial stimulation have been introduced to obviate the necessity for thoracotomy. One has been the introduction of a myocardial electrode by Thevenet et al. (1958) through a blind percutaneous puncture. This technique carries with it the risk and uncertainty of a blind puncture of the heart plus the original limitations of cutaneous infection and ultimate ineffectiveness of stimulation within a month or two.

The second modification, by Furman and Schwedel, is the introduction of an *intracavitary wire electrode* by way of a cardiac catheter passed up a vein of the forearm into the right ventricle. Direct cardiac stimulation at voltages less than 10 volts without pain was carried out by him in one patient with Stokes-Adams disease for over 3 months. Local skin infection is a problem with this technique also, but effective stimulation is apparently possible for longer periods than with the myocardial electrode. The additional possible complications of thromboembolism and trauma to the right-sided endocardium or valves were not encountered; anticoagulant therapy was maintained throughout the entire period of stimulation. This procedure is clearly most useful in patients with Stokes-Adams disease with persistent seizures, who cannot tolerate external electric stimulation. Under these circumstances, the risks of the procedure are clearly acceptable. It is equally clear, however, that this technique cannot be used indefinitely for the permanent maintenance of patients with Stokes-Adams disease throughout their lifetime. Better techniques of management, by pharmacologic agents or by electronic pacemakers that may be buried in the body and operate effectively and indefinitely, are under investigation for this ultimate goal.

cardia most often occur in subjects under 40 *years of age,* those of ventricular tachycardia are more common after 40. Complete heart block, although usually found in persons over 50, may be noted in childhood, when its origin *is congenital, diphtheritic,* or rheumatic. Pre- [illegible] may occur at any age, although [illegible]

[illegible] mitral disease or thyrotoxicosis, is more common [illegible] females [illegible]

[illegible] bladder disease, *chronic* gastrointestinal disorder, or renal calculus is in favor of extrasystole. A history of coronary occlusion or precordial pain suggests the possibilities of ventricu*lar extrasystoles, ventricular tachycardia,* or AV block.

DRUGS AND ADDICTIONS Overdigitalization may provoke extrasystoles, *especially with a bigeminal type of sinus bradycardia,* sinus arrhythmia, or AV block. Long-standing or excessive administration of epinephrine or ephedrine for bronchial asthma, *of thyroid extract for obesity,* or of atropine, quinidine, or barium chloride may elicit extrasystoles, sinus tachycardia, or AV block. Excess of tea, coffee, or tobacco may be *responsible* at times for troublesome arrhythmias.

Specific Interrogation. PRECIPITATING FACTORS Ventricular extrasystoles, heart block, ventricular tachycardia, *and sinus tachycardia* are common after myocardial infarction, sinus bradycardia, sinus tachycardia, and disturbances of conduction are often *observed during* or after diphtheria, *influenza,* pneumonia, mumps, *or jaundice.* Extrasystolic beats and paroxysms of supraventricular tachycardia may accompany gastrointestinal or emotional *disorders.*

ONSET The *onset of arrhythmia* is dramatically *sudden* or instantaneous in paroxysmal tachycardia (especially supraventricular), *it is* gradual in sinus tachycardia, *and at times in* ventricular tachycardia, *in the last,* it may be preceded by premature contractions.

ASSOCIATED SYMPTOMS An abnormal *cardiac* rhythm may be asymptomatic *or may* be associated with one or more symptoms. Palpitation is the most *common* symptom of all and is frequently noted with *extrasystoles,* atrial fibrillation, paroxysmal tachycardia, and *sinus tachycardia.* A disagreeable thump or thud, when described after a *pause, suggests a postextrasystolic* beat. Episodes of *convulsions, associated* with loss of consciousness and cyanosis *(Stokes-Adams* attacks), *are suggestive of* AV block. *Polyuria,* or frequency *during attacks,* suggests paroxysmal tachycardia. Yawning, sighing, and a feeling of exhaustion are commonly *associated with the sinus tachycardia* of neurocirculatory asthenia and cardiac neurosis. A sense of fullness in the neck, occurring *intermittently, is an uncommon* manifestation of extrasystolic beats and is due to regurgitation of blood from the right atrium to the jugular veins. *Dizziness or faintness may occur during* attacks of paroxysmal tachycardia or "runs" of extrasystolic beats. Severe precordial pain may arise during a prolonged attack of *paroxysmal* tachycardia.

TERMINATION OF ATTACK. The termination of attacks *is* gradual in *sinus rhythms and is usually sudden in paroxysmal* supraventricular tachycardia. When an attack *is* stopped by stooping or bending down, holding of the breath, or *mechanical stimulation of the vagus nerve,* supraventricular paroxysmal tachycardia is likely.

Pulsatory Phenomena. HEART RATE. *Since in extrasystoles or atrial fibrillation* some pulses may be too feeble to be transmitted to the radial artery, the heart rate *must be determined* by auscultation at the apex, not at the wrist. Cardiac rates of below 40 beats per minute suggest either complete or severe *incomplete* AV block or nodal rhythm; regular rates of over 160 *favor paroxysmal tachycardia.* Sinus tachycardia and atrial flutter are usually associated with rates below 160 per minute. A persistent, regular, and *unvarying cardiac* rate of about 150 *per minute,* particularly in an elderly *subject,* suggests a 2:1 atrial flutter.

PULSE DEFICIT. When the *cardiac* rate, determined at the apex, exceeds that of the radial *pulse* rate by 10 beats or more, a diagnosis of atrial fibrillation is justified. A pulse deficit, however, may also arise with ventricular extrasystoles, provided the pulses of the ectopic beats are too feeble to be conveyed to the radial pulse.

JUGULAR PULSE. *Neck* vein pulsations are of great diagnostic value, especially when studied *in conjunction* with the arterial pulse. For in-

on the site of origin and nature of the mechanism involved, has been more or less universally accepted of late:

ABNORMAL CARDIAC MECHANISMS OR RHYTHMS

1. Sinus Mechanisms
   - 1.1 Sinus Tachycardia
   - 1.2 Sinus Bradycardia
   - 1.3 Sinus Arrhythmia

STUDY OF ARRHYTHMIAS

Nowhere, in the entire field of cardiology, has electrocardiography been exploited to greater advantage than in the interpretation of cardiac arrhythmia. The exact mechanism of many a hitherto obscure irregularity of the heart has been unraveled by resort to this method of instrumental investigation. Although the prime role of electrocardiography in the diagnosis of abnormal cardiac rhythms and its unquestioned superiority over other methods of examination have been securely established in recent years, the informative value of a good history and thorough clinical examination in the understanding of cardiac arrhythmias has not been sufficiently appreciated. Since the subject of electrocardiographic interpretation of cardiac irregularities has been dealt with at great length in various chapters of Vol III of *Cardiology*, the present paper deals with the clinical differentiation only. The majority of cardiac arrhythmias, as a matter of fact, are clinically recognizable, provided a systematic method of cross examination or history taking and thorough physical examination are undertaken.

The following scheme of investigation, having proved valuable in the majority of cases, is recommended for routine adoption:

- I. History
  - *A.* General (age, sex, predisposing factors, etc.)
  - *B.* Specific (regarding the various characteristics of the cardiac arrhythmia itself, e.g., onset, duration, associated symptoms and cessation of attack)
- II. Physical examination
  - *A.* Observations of pulsatory phenomena
    1. Cardiac rate and rhythm
    2. Arterial pulse
    3. Venous pulsations
  - *B.* Examination of the heart
    1. Presence or absence of organic heart disease
    2. Apex beat
    3. Heart sounds
  - *C.* Special methods of clinical examination
    1. Effect of exercise
    2. Effect of deep respiration and of apnea
    3. Effect of carotid sinus pressure
    4. Levine's method
  - *D.* Examination of other systems
- III. Instrumental investigation
  - *A.* Fluoroscopy
  - *B.* Electrocardiography
  - *C.* Phonocardiography

General Interrogation. AGE. While certain arrhythmias, such as sinus arrhythmia, paroxysmal supraventricular tachycardia, and atrial ex[illegible] trasystoles, are common in the young, paroxysmal ventricular tachycardia, ventricular extrasystoles, and atrial flutter show a predilection for elderly subjects. Sinus arrhythmia is common in infants, children, and the aged. Attacks of supraventricular paroxysmal tachy-

breath may remove the irregularity of sinus arrhythmia, bring out latent extrasystoles, and help in the differentiation of pulsus paradoxus from pulsus alternans.

CAROTID SINUS STIMULATION. COMPRESSION OF THE EYEBALLS. These maneuvers have no effect on ventricular rate in complete heart block, atrial fibrillation, or ventricular tachycardia, they tend to cause further slowing of the heart rate in incomplete AV block, they frequently terminate an attack of paroxysmal supraventricular tachycardia, they bring about a gradual and transitory slowing of the heart rate in sinus tachycardia, they may cause a sudden halving of the rate in atrial flutter, even though, in most cases, they have only a moderate and temporary effect, particularly if there is variable block.

LEVINE'S METHOD "Tapping of the foot in rhythm with the heart" has been recommended by Levine as a useful method of differentiating supraventricular from ventricular tachycardia (even a slight irregularity of rhythm favoring the latter), atrial from ventricular extrasystoles (the postextrasystolic pause being strictly compensatory in the latter), SA from partial AV block (the pause, in the latter, does not correspond in length to two cardiac cycles), and atrial fibrillation from multiple extrasystoles (all pauses in the latter are preceded by small and rapid pulsations, i e , premature beats)

Instrumental Investigations. FLUOROSCOPY Fluoroscopy may afford diagnostic clues in arrhythmias Rapid and irregular undulations of the atria without proper contractions may be observed in atrial fibrillation Synchronous contraction of the atria and ventricle, with additional contractions of the atria during the long diastolic pauses, is suggestive of *AV block*. In atrial flutter, rapid and regular *contractions of* the atria may be visible in the right anterior oblique position

ELECTROCARDIOGRAPHY This method is capable of supplying information of immense diagnostic value and should be employed in every single case of cardiac arrhythmia; however, in many cases it serves only to confirm or exclude the diagnosis, after all clinical sources of information have been fully used.

CLINICAL CLASSIFICATION OF CARDIAC ARRHYTHMIAS

The following eight types of cardiac arrhythmias are recognizable clinically, on the basis of rhythm, rate, and perceptibility of cardiac pulsation (Vakil, 1954)

1. Regular rhythm with slow rate (rhythmic bradycardia)
2. Regular rhythm with rapid rate (rhythmic tachycardia)
3. Regular rhythm with normal rate
4. Regular rhythm with unequal force of beats
5. Irregular rhythm with slow rate (arrhythmic bradycardia)
6. Irregular rhythm with rapid rate (arrhythmic tachycardia)
7 Irregular rhythm with normal rate
8 Clinically silent (imperceptible) rhythm

Type I: Regular Rhythm with Slow Rate (1) Sinus bradycardia, (2) nodal rhythm, (3) incomplete (2:1 or 3:1) AV block, (4) complete AV block, (5) atrial flutter with 4:1 or 5:1 block, (6) atrial fibrillation with nodal rhythm.

A clinical diagnosis is possible, in the majority of cases, by simultaneous study of radial artery and jugular vein pulsations, and by palpation and *auscultation of the heart.*

Type II: Regular Rhythm with Rapid Rate. (1) Sinus tachycardia, (2) paroxysmal supraventricular tachycardia, (3) paroxysmal ventricular tachycardia, (4) 2:1 type of atrial flutter, (5) preexcitation (Wolff-Parkinson-White) syndrome.

A clinical diagnosis is facilitated by paying attention to the following features: (*a*) past history of similar attacks, (*b*) mode of onset of arrhythmia, (*c*) mode of termination, (*d*) duration of attack, (*e*) rate of beating, (*f*) rhythm, (*g*) venous pulsations of the neck, (*h*) influence of exercise, respiration, carotid sinus pressure, and posture.

Type III. Regular Rhythm with Normal Rate. A *regular rhythm* with a normal rate of 70 to 80 beats per minute need not necessarily imply a *normal* sinus rhythm, as certain pathologic mechanisms are compatible with such a state. (1) first-*degree AV block*, with increased AV conduction time, (2) intra-atrial block, (3) intraventricular *conduction* defect, such as bundle branch block or arborization block, (4) paroxysmal tachycardia (*usually* supraventricular) with 2:1 block, (5) atrial flutter with 4:1 block, (6) *nodal rhythm,* when the cardiac rate is not *unduly slow*, (7) complete AV block (rarely) with *unusually high* idioventricular rate (*e g*, *congenital or diphtheritic*), (8) sinus tachycardia, with *alternating* block (either SA or AV block).

Electrocardiography is usually essential for diagnosis of this group of cases

Type IV: Regular Rhythm with Unequal Force of Beats. (1) Pulsus *alternans*, (2) pulsus paradoxus, (3) regularly alternating *extrasystoles*.

Clinical diagnosis is usually possible on the basis of "spacing" of the beats.

stance, in *sinus rhythm*, normal a, c, and v waves are seen, together with a characteristic systolic collapse of the jugular vein synchronous with each heart beat. On the other hand, in *nodal rhythm*, there is a large systolic pulsation or wave with each beat, because of simultaneous contraction of the right atrium and ventricle. In the *first-degree AV block*, with increased P-R interval, a characteristic delay occurs between the a and the c-v waves of the venous pulse; in *partial heart block*, a number of a waves are visible between the other waves and the degree of block can be determined by counting the ratio of a waves to radial pulses. In *complete heart block*, besides the phenomena of extra a waves, there are occasional large venous pulsations (familiarly known as "cannon waves"), owing to simultaneous contraction of atria and ventricles. In atrial fibrillation, even with slow rates, the absence of a waves reveals the diagnosis. In *atrial flutter*, typical, rapid, regular waves are visible during the diastolic pauses. Multiple and frequent extrasystoles can be differentiated from atrial fibrillation because the systolic collapse of the vein that occurs in the latter tends to decrease or disappear in the former.

Examination of the Heart. *Sinus bradycardia, sinus arrhythmia,* and *sinus tachycardia* are [illegible] tions and *paroxysmal supraventricular tachycardia* are more often associated with normal hearts than with diseased ones Diseases of the gastrointestinal and biliary tracts may induce reflex extrasystoles. *Paroxysmal ventricular tachycardia* seldom occurs except with severely damaged hearts *Atrial fibrillation* may be connected with mitral stenosis, coronary sclerosis, or hyperthyroidism, in the latter case, fibrillation tends to be paroxysmal. In rheumatic fever, first-degree heart block is common and is of diagnostic significance. Diphtheria may cause a varying degree of AV block. Atrial flutter and heart block may be associated with congenital heart disease. A high systolic and a low diastolic pressure is usual in complete heart block.

CHARACTER OF APEX BEAT. Palpation of the cardiac apex may suggest the existence of bundle branch block in the event of a bifid or double thrust, and of pulsus alternans in the event of alternately vigorous and feeble pulsations. Detection of a displaced apex beat or thrill at the apex may indirectly suggest the nature of the arrhythmia, by disclosing the presence or nature of organic heart disease.

HEART SOUNDS. The nature of an arrhythmia may be suggested by careful auscultation of the heart sounds, particularly at the apex. In *nodal rhythm*, the 1st sound tends to become louder each time that the atria and ventricles contract simultaneously. While in *paroxysmal atrial tachycardia*, the intensity of the 1st sound is constant from beat to beat, in *ventricular tachycardia* it may show a characteristic variation. In *atrial fibrillation and flutter* (particularly in the latter), the 1st sound tends to vary in intensity; in atrial fibrillation, the 2d sound may be absent, whenever the ventricular contraction fails to open the semilunar valves. In *atrial flutter*, extra sounds, due to audible atrial contractions, may be heard during diastole. In *first-degree AV block*, either the 1st sound becomes attenuated in intensity or an extra sound is heard in diastole because of early atrial contraction. In *second-degree AV block*, the 1st sound may be preceded by an atrial sound, a phenomenon never observed in SA block. In *complete AV block*, there is a slow but regular ventricular rate of 20 to 40 beats per minute, with variations in intensity of the 1st sound, which assumes at times a loud and explosive character, commonly referred to as *bruit de cannon*. Splitting of the 1st and 2d sounds may occur in *bundle branch block;* a diastolic triple rhythm in conjunction with pulsus alternans may also suggest this condition.

Special Methods of Clinical Examination. EFFECT OF EXERCISE. Acceleration of the pulse after exercise, atropine, or amyl nitrite, by its action on the cardiac arrhythmia, may supply information of diagnostic value. Although exercise tends to increase the cardiac rate in sinus tachycardia, it has no effect on the rate of paroxysmal tachycardia The *irregularity of the pulse in atrial fibrillation* is usually accentuated by exercise. Exercise has little or no effect on the ventricular rate of complete heart block, but may cause the ventricular rhythm of the Wenckebach type of AV block *to return to normal* In atrial *flutter*, the ventricular rate *may be suddenly doubled by exercise*, in most *rhythms*, the rise of rate tends to be gradual.

EFFECT OF RESPIRATION. Sustained and deep respiratory effort, whether inspiratory or expiratory, may terminate an attack of supraventricular tachycardia by *stimulating* the vagus nerve. The *simple maneuver* of holding the

Type V: Irregular Rhythm with Slow Rate (Arrhythmic Bradycardia). (1) Sinus arrhythmia with sinus *bradycardia, (2) sinus* bradycardia *with sinus* pauses or SA block, (3) sinus bradycardia with extrasystoles (atrial, nodal, or ventricular), (4) nodal arrhythmia, (5) incomplete AV block with frequent dropped beats, (6) unstable AV *block,* (7) atrial flutter, with variable *and high degree* of block, (8) atrial fibrillation *with slow ventricular* response.

In the majority of cases, a clinical diagnosis is possible through careful interrogation and examination of the patient.

Type VI: Irregular Rhythms *with Rapid* Rate (Arrhythmic Tachycardia). (1) *Atrial* fibrillation, *(2) atrial flutter, (3) sinus tachycardia with multiple* extrasystoles, (4) AV dissociation (interference dissociation), (5) *paroxysmal* ventricular tachycardia

Clinical *diagnosis* is usually facilitated by (*a*) artificially raising the cardiac rate with exercise, atropine, or amyl nitrite, (*b*) careful palpation of the pulse, for timing of beats, "pulse deficit," and "dominant rhythm"; (*c*) study of the 1st sound for variations in intensity.

Type VII. Irregular Rhythm with Normal Rate. (1) *Sinus arrhythmia,* (2) normal sinus rhythm *with extrasystoles* (atrial, nodal, or ventricular), (3) SA block, (4) sinus pauses, (5) partial AV *block* with irregular dropping of beats, (6) Wenckebach type of AV block, (7) interference dissociation.

Clinical diagnosis is usually possible after a *careful interrogation* and examination of the patient.

Type *VIII. Clinically* Silent (Imperceptible) *Rhythms. This* group of arrhythmias is characterized by the complete absence, clinically, of all pulsatory phenomena, arterial, venous, and cardiac (1) *severe tachycardia* (e g, 1:1 atrial flutter), (2) *ventricular flutter,* (3) ventricular fibrillation, (4) paroxysmal tachycardia with ineffective systolic contractions (rare), (5) severe shock (e g, after coronary thrombosis), (6) long sinus pauses or cardiac standstill (e g, AV block with Stokes-*Adams syndrome).*

A careful study of symptoms and signs may furnish the required information, otherwise, an electrocardiogram is indicated for diagnosis.

CONCLUSION

Despite the apparent complexity of cardiac arrhythmias, careful history taking, physical examination, and simple methods of clinical investigation often make it possible to recognize the nature of cardiac arrhythmias without having recourse to specialized methods of instrumental investigation, such as electrocardiography.
